1. Introduction

There is discrepancy between the number of known Supernova Remnants (SNRs, about 265) and the number predicted by theory (about $10^3$ Galactic SNRs, Li et al. 1991; $\sim 10^4$ SNRs, Tammann et al. 1994). This has been considered the result of selection effects in current sensitivity-limited surveys, which favor the discovery of the brighter remnants (e.g. Green 2005; Tian & Leahy 2004). Survey data from observations that combine high sensitivity and resolution with low radio frequencies are becoming the richest modern hunting grounds for new SNRs. Some new SNRs have been discovered from the 90 cm Very Large Array survey of the inner Galaxy (Brogan et al. 2006) and the Canadian Galactic Plane Survey (CGPS) of the outer Galaxy (Kothes et al. 2005). In this paper, we present the discovery of a faint shell-type SNR, through its association with polarized radio emission and a steep-gradient radio spectrum.

2. Observations and Analysis

The radio continuum, H\textsc{i} and CO emission data sets come from the CGPS, which is described in detail by Taylor et al. (2003). These data are mainly based on observations from the Synthesis Telescope (ST) of the Dominion Radio Astrophysical Observatory (DRAO). The synthesized beam of the ST at 21 cm wavelengths is roughly $72'' \times 59''$, and at 74 cm is $3.3 ' \times 2.8'$. The velocity resolution in the 21 cm line is 1.32 km s$^{-1}$, gridded to 0.82 km s$^{-1}$ per channel. DRAO ST observations are not sensitive to structures larger than an angular size scale of about $3.3^\circ$ at 408 MHz and $56'$ at 1420 MHz, thus for a complete sampling of spatial structures, the CGPS includes data from the 408 MHz all-sky survey of Haslam et al (1982), and the Effelsberg 1.4 GHz Galactic plane survey of Reich et al. (1997). Stokes U and Q data used here include all spatial-scales, by including observations from the DRAO interferometer, the Effelsberg Medium Latitude Survey (preliminary data, courtesy W. Reich and group at MPIfR), and by the DRAO 26-metre Survey (Wolleben et al. 2006). Short-spacing H\textsc{i} line data are from the single-antenna survey of Higgs & Tapping (2000), and have a resolution of $36'$. IRAS data reprocessed for inclusion in the CGPS are also used for our study (Cao et al. 1997, Kerton & Martin 2000).

3. Results

3.1. Radio Continuum Emission

The new SNR has an average angular size $62'$ (EW $\times$ NS $70' \times 54'$, Fig. 1), and is located west of the nearby bright SNR CTB 109. South is another faint SNR G107.5-1.5 (Kothes 2003), and to the southwest is the bright radio H\textsc{ii} region Sh2-142 ($\ell=107.1^\circ$, $b=-0.9^\circ$). Two bright compact H\textsc{ii} regions (Sh2-146 & Sh2-148) are immediately adjacent to the east and southeast of G108.2 $-0.6$. The molecular cloud of Sh2-152 is found off the SE edge at 7 o'clock.

The SNR is characterized as a filled-centre region of diffuse emission (0.5 K above background at 1420 MHz), brightening slightly towards its perimeter to 0.8 K above background at the eastern and southern edges. The 1420 MHz spectrum is shown in Fig. 1.
Fig. 1. The CGPS continuum maps at 408 MHz (left) and 1420 MHz (right) are shown in the first row. The box covering G108.2-0.6 is used for T-T plots spectral index. The position of pulsar B2255+58 and the direction of North (N) and South (S) are marked on the right plot. The second row presents the polarized appearance of G108.2−0.6, as seen at 21 cm in the CGPS. The polarized intensity map at left shows distinct emission (a small circular area; see text) from within the continuum bounds of G108.2−0.6 (represented by the large circle, as described in the text). The polarized-angle map at right shows that the SNR lies within a distinct region of uniform, negative rotation angle. Both maps have been smoothed to 3-arcminute resolution. Note the distinction of G108.2−0.6 from the nearby CTB 109 (contour at 9 K; ℓ=109.1°, b=-1.0°), which exhibits less polarized intensity, and a uniform rotation angle that is more positive. Polarization data are from the CGPS and include preliminary data from the Effelsberg Medium Latitude Survey.

The shell-type structure of G108.2−0.6. The shell’s elliptical outline is nearly completely traced by filaments in the 1420 MHz map. The brightest filament of the SNR lies along its southwest boundary. A 0°.6-radius circle centred on ℓ=108.14°, b=-0.81° well delimits the object’s nearly-circular appearance in radio continuum. Several compact sources within the SNR are resolved in both the 1420 MHz and the 408 MHz maps.

21 cm polarized emission is seen towards G108.2−0.6 (the lower plots of Fig. 1). The polarized emission is confined mainly to the low galactic latitude part of the remnant. A circular area of fairly well defined polarized intensity (PI, about 0°.4 in diameter) is centred on the 408 MHz data, with a rotation angle of about 20°. Positive polarization is found in the Wright et al. (1984) radio observations near the same position, and in the M91 (1972) data, which show a similar pattern of polarization at 843 MHz. A 0°.6-radius circle centred on ℓ=108.37°, b=-0.975° well delimits the object’s nearly-circular appearance in radio continuum. Several compact sources within the SNR are resolved in both the 1420 MHz and the 408 MHz maps.
thermal and non-thermal brightness temperature (made by assuming their radio spectra follow $\alpha = -0.1$ and $-0.5$, respectively), this patch spatially correlates with the brightest non-thermal emission from the SNR, which seems to form a crescent-like filament that wraps partially around the circular patch of PI (lower left of Fig. 1). The SNR’s association with polarization is especially evident in a map of polarization angle (PA, the lower right of Fig. 1), which show the SNR’s continuum shell encircles a region of roughly uniform angle ($-39^\circ \pm 3^\circ$) over the SNR’s face. The angle is uniformly negative with respect to the mean background angle (typically $-28^\circ$ to $-34^\circ$), and is also distinguished from the nearby CTB 109 ($-23^\circ$, positive rotation with respect to the background). Polarized radio emission in SNRs originates with synchrotron emission (electrons interacting with the compressed ISM magnetic field), so some correlation of total power with polarized intensity and an ordering in angle makes sense (ignoring random depolarization and rotation by the intervening ISM).

Notwithstanding the intriguing observed PI and PA features, it is difficult to firmly conclude that the polarized emission actually belongs to G108.2$-$0.6, as the larger region around it also shows random patches of PI of approximately the same relative brightness (though these patches are not correlated with any features in total power).

### 3.2. Flux Density and Spectral Index

The 1420 MHz CGPS map has many compact sources overlapping the face of G108.2$-$0.6. Bright compact sources affect the measured integrated flux densities for G108.2$-$0.6 and its measured spectral index. It is difficult to separate the SNR from diffuse background emission at 408 MHz due to both lower resolution of the observations and fainter emission of the new SNR at 408 MHz. We can reliably correct for the effects of compact sources by subtracting them from the 1420 MHz map only (see Fig. 2), and then determining spectra by employing the special T-T plot spectral analysis method of Leahy (2006). The T-T plot method is described more generally in the paper of Tian & Leahy (2005). For the T-T plot spectral index analysis, we select a single region covering the whole G108.2$-$0.6 shown in Fig. 1, which yields the T-T plot shown in the Fig. 3. Since compact sources are subtracted from the 1420 MHz map only, compact sources show up as a vertical line of points, with 408 MHz flux density but no 1420 MHz flux density. We obtain a T-T plot spectral index of $\alpha = -0.5 \pm 0.1$ ($S_\nu \propto \nu^\alpha$) between 408 MHz and 1420 MHz, a typical index for shell-type remnants.

The integrated flux density of the new SNR is $6.6 \pm 0.7$ Jy at 1420 MHz (ie $\Sigma_{1420}\ MHz = 2.4 \times 10^{-22}$ Watt m$^{-2}$Hz$^{-1}$ sr$^{-1}$) and $11.5 \pm 1.2$ Jy at 408 MHz, corrected for flux densities from compact sources within the SNR. Its flux density-based spectral index is $-0.45 \pm 0.13$ which is consistent with its T-T plot spectral index. We also check the 2695 MHz Effelsberg map of the region around G108.2$-$0.6, and find that G108.2$-$0.6 is marginally visible at this frequency (Fürist et al. 1990). This supports the case of a steep spectrum. In terms of its radio surface brightness, this SNR is one of the 6 faintest known SNRs (Green, 2006). Two of them are in regions towards the anti-centre at high latitudes (G182.4+4.3, Kothes et al. 1998; G156.2+5.7, Reich et al. 1992), three others are discovered by the CGPS survey in the inner parts of the Galaxy (G108.2$-$0.6, Kothes et al., G96.0+2.0, G217.2+12.8, Green et al., 2006).
Fig. 2. The plot shows a zoomed 1420 MHz map with compact sources subtracted.

Fig. 3. 408-1420 MHz T-T plot for the new SNR where compact sources have only been subtracted at 1420 MHz map for the plot. The fitted lines show the spectral slopes for $\alpha=0.4$, 0.5 and 0.6.

Kothes et al. 2005). Brogan et al. (2006) discovered 35 SNR candidates from the 90 cm VLA survey of the inner Galaxy (15 of 35 candidates are very confident), but their surface brightnesses are in the range of $\Sigma_{1\text{GHz}}=(1-15) \times 10^{-21}$ Watt m$^{-2}$Hz$^{-1}$ sr$^{-1}$. G108.2-0.6 is a large anti-centre object near the Galactic plane. Its discovery partly supports Kothes et al.(2001)'s conclusions that a survey with the characteristics of the CGPS can identify faint extended SNRs amongst the confusing thermal emission near the Galactic plane.

3.3. HI, CO, Infrared, X-ray and Optical Emission

We have searched the CGPS radial velocity range for features in the H$\text{I}$ and $^{12}$CO lines ($^{12}$CO data from the Five College Radio Astronomy Observatory $^{12}$CO (J=1-0) outer galaxy survey, Heyer et al. 1998) which relate to the morphology of G108.2–0.6. We find suggestive correlations with H$\text{I}$ features in the velocity range $-53$ to $-58$ km s$^{-1}$. Fig. 4 shows map of H$\text{I}$ emission integrated over channels from $-53$ to $-58$ km s$^{-1}$. There are no apparent $^{12}$CO features associated with the remnant. We have checked IRAS 12, 25, 60 and 100$\mu$m maps of the region surrounding G108.2–0.6 and found indications at 12$\mu$m and 25$\mu$m.
emission surrounding G108.2−0.6, particularly at 60 µm (see Fig. 5). The main infrared emission is close to the eastern boundary and away from the SNR. Two bright regions of compact IR emission, H\textsc{ii} regions Sh2-146 and Sh2-148, partly overlap on the east and southeast frontiers of G108.2−0.6, respectively.

We have examined the ROSAT All-Sky Survey images (http://www.xray.mpe.mpg.de/cgi-bin/rosat/rosat-survey/), and find no obvious X-ray emission in the area of new SNR. Optical images from the Palomar Digitized Sky Survey (http://skyview.gsfc.nasa.gov/cgi-bin/skvadvanced.pl) show no optical filamentary emission related with the new SNR.

4. Discussion

4.1. The Distance

With a radial velocity of $-55\pm 3$ km s$^{-1}$ for the H\textsc{i} structure around G108.2−0.6, and the assumption that this derives purely from circular galactic rotation, one estimates the SNR’s kinematic distance to be $\sim 5.3$ kpc assuming circular velocity $V_R=V_0=210$ km s$^{-1}$ that is constant with Galactocentric distance, and $R_0=7.6$ kpc, as in Eisenhauer et al.(2005). However, as shown by Foster & MacWilliams (2006), the conversion of circular velocity to any other parameter (e.g. distance) may not be valid.
Fig. 6. The line-of-sight (LOS) velocity field towards the SNR (top panel), as determined from the H\textsc{i} modelling method of Foster & MacWilliams (2006). The fit of the synthetic model spectrum to the observed one is shown at bottom. The triangles in the velocity field mark the velocity and distance of G108.2\textdegree\textminus0.6 reported in this paper (−55 km s\textsuperscript{−1}); the ambiguous distance results from the velocity reversal caused by the spiral shock (the front of which is at 3.1 kpc). Density-wave streaming motions are terminated beyond the Perseus arm, and no model component for the Outer Arm is included here (as this LOS passes through very little of the far outer disk due to the disk’s upward warp). The LOS component of circular rotation only (power-law of index −0.34; a gently-declining rotation curve) is shown as the smooth curve on the velocity field. An spin-temperature of 200 K was assumed to make the H\textsc{i} disk optically-thin, and a turbulent dispersion width of $\sigma_v = 4$ km s\textsuperscript{−1} was used.

can lead to serious overestimation of a young object’s distance, especially if that object is associated with the more enigmatic non-circular motions of the velocity field (like those introduced by the spiral shock, Roberts 1972). We therefore turn to the distance method of Foster & MacWilliams (2006). The method fits a model of the density and velocity field to the observed H\textsc{i} distribution, and calculates a kinematic distance from the fitted model. The model is not based on detailed hydrodynamical calculations, but rather is an analytical tool to functionally reproduce any reasonable geometric Galactic H\textsc{i} density and velocity distribution through the disk. The model includes density and dynamics of the gas’ linear response to a density wave (Lin et al. 1969), modified analytically to reproduce the non-linear behaviour of the velocity field (including the shock that precedes a spiral arm). As type Ib/II SNe are expected to occur near their progenitor’s formation site (since the lifetime of massive stars is very short compared to their Galactic rotation periods), this distance method is particularly applicable to Galactic SNRs, which likely retain
kinematics of the spiral shock (presumably the place of formation of massive stars that give rise to them).

A range of fitted models in the line-of-sight $\ell = 108-109^\circ, b = -0.4-1.0^\circ$ (see Fig. 6) shows that the velocity range of $-50$ to $-60$ km s$^{-1}$ is covered by the Perseus arm spiral shock front. G108.2$-0.6$ is either just beyond this front (at $r = 3.2 \pm 0.6$ kpc, or Galactocentric $R = 9.14$ kpc) or has migrated through the Perseus arm ($R_{Per} = 9.27$ kpc) to a current position on its outer edge at $r = 4.4$ kpc ($R = 9.93$ kpc). For a relative angular speed of $(\Omega - \Omega_p) = 1-2$ km s$^{-1}$ kpc$^{-1}$ (pattern speed $\Omega_p = 20$ km s$^{-1}$ kpc$^{-1}$), this migration would take on the order of 40-80 million years, longer than the lifetime of a massive progenitor which formed in the arm. Therefore, the nearer distance is preferred.

Since this SNR shares a similar velocity and distance with nearby CTB 109 (3 kpc, Kothes et al. 2002), one presumes they may be related. However, CTB 109 is physically smaller than G108.2$-0.6$ (24 pc versus 58 pc respectively). Thus, G108.2$-0.6$ is perhaps simply a more evolved remnant, or is evolving into a different medium. Its progenitor may have been part of the family of stars that formed in this complex area (which would include the progenitor of CTB 109).

4.2. G108.2$-0.6$ and PSR J2257+5909

PSR J2257+5909 is close to the northeastern edge of G108.2$-0.6$ (Fig. 1), has a large dispersion measure distance of 4.5 kpc from the Cordes & Lazio (2002) electron density model. This distance is larger than that estimated for G108.2$-0.6$. Recent timing measurements (Zou et al. 2005) give PSR J2257+5909's proper motion $550 \pm 120$ km s$^{-1}$ ($\mu_{\alpha} = 24 \pm 6$ mas yr$^{-1}$, $\mu_{\delta} = -7 \pm 5$ mas yr$^{-1}$). These show that PSR J2257+5909 is probably not associated with G108.2$-0.6$.

5. Conclusion

We have discovered a new SNR G108.2$-0.6$ using the data of the CGPS including Stokes I, Q, and U radio continuum, H$\alpha$, CO and infrared emission. The identification is based on its shell-type structure, a more-or-less typical non-thermal index of $\alpha = -0.5$. Based on a spatial correlation between H$\alpha$ emission features and the SNR’s continuum boundary, G108.2$-0.6$ is located in the Perseus arm shock at a distance of about 3.2 kpc. Its integrated flux density is $6.6 \pm 0.7$ Jy at 1420 MHz and $11.5 \pm 1.2$ Jy at 408 MHz after subtraction of background and compact sources within the SNR. In X-ray and optical maps we find no significant emission from the SNR.

Acknowledgements. We would like to thank Wolfgang Reich and the polarization group at the Max-Planck-Institut für Radioastronomie (MPIfR) for allowing us access to preliminary Effelsberg Medium Latitude Survey polarization data. We acknowledge support from the Natural Sciences and Engineering Research Council of Canada. TWW appreciates support from the Natural Science Foundation of China. We thank Dr. R. Kothes at the DRAO for helpful discussion. The DRAO is operated as a national facility by the National Research Council of Canada. The Canadian Galactic Plane Survey is a Canadian project with international participation.
