The problem of closing the detection loophole with asymmetric systems is addressed. We show that, for the Bell inequality \( I_{322} \), a minimal detection efficiency of 43\% can be tolerated for one of the particles, if the other one is always detected. Based on a connection between local hidden variable models exploiting the detection loophole and models using classical communication, we derive a lower bound on the necessary detection efficiency and show that some non-maximally entangled states cannot be simulated with one bit of communication. Furthermore we study the influence of noise and discuss the prospects of experimental implementation.

Non-locality is one of the most striking properties of quantum mechanics. Two distant observers, each holding half of an entangled quantum state and performing appropriate measurements, share correlations which are non-local, in the sense that they violate a Bell inequality \[1\]. In other words, those correlations cannot be reproduced by any local hidden variable (lhw) model. All laboratory experiments to date have confirmed quantum non-locality \[2,3,4,5,6\]. There is thus strong evidence that Nature is non-local. However, considering the importance of such a statement, it is crucial to perform an experiment free of any loopholes, which is still missing today. Another motivation comes from quantum information science, where the security of some quantum communication protocols is based on the violation of Bell inequalities \[7\].

Performing a loophole-free Bell test is quite challenging. One first has to insure that no signal can be transmitted from one particle to the other during the measurement process. Thus the measurement choice on one side and the measurement result on the other side should be spacelike separated. If this is not the case, one particle could send some information about the measurement setting it experiences to the other particle. This is the locality loophole \[8\]. Secondly the particles must be detected with a high enough probability. If the detection efficiency is too low, a lhw model can reproduce the quantum correlations. In this picture a hidden variable affects the probability that the particle is detected depending on the measurement setting chosen by the observer. This is the detection loophole \[9\].

In practice, photon experiments have been able to close the locality loophole \[3,4,5\]. However the optical detection efficiencies are still too low to close the detection loophole. For the Clauser-Horne-Shimony-Holt (CHSH) \[10\] inequality, an efficiency larger than 82.8\% is required to close the detection loophole with maximally entangled states. Surprisingly, Eberhard \[11\] showed that this threshold efficiency can be lowered to 66.7\% by using non-maximally entangled states. On the other hand an experiment carried out on trapped ions \[6\] closed the detection loophole, but the ions were only a few micrometers apart. It would already be a significant step forward to close the detection loophole for well separated systems. Recently new proposals for closing both loopholes in a single experiment were reported \[12,13\].

In this paper we focus on asymmetric setups, where the two particles are detected with different probabilities. This is the case e.g. in an atom-photon system: the atom is measured with an efficiency close to one while the probability to detect the photon is smaller. Intuition suggests that if one party can do very efficient measurements, then the minimal detection efficiency on the other side should be considerably lowered compared to the case where both detectors have the same efficiency. Experimentally this approach might be quite promising, since recent experiments have demonstrated atom-photon entanglement \[14,15\] and violation of the CHSH inequality \[16\]. In the following, after presenting the general approach to the study of the detection loophole in asymmetric systems, we focus on the case where one of the systems is detected with efficiency \( \eta_A = 1 \) and we compute the threshold efficiency \( \eta_B^{th} \) for the detection of the other system. The best results are obtained for the the three-setting \( I_{3322} \) inequality \[17\]. In analogy to Eberhard’s result \[11\], we show that non-maximally entangled states require a lower efficiency; moreover here, the threshold goes down to \( \sim 43\% \). After studying different noise models, we take advantage of a connection with the information-theoretical problem of simulation of entanglement. In particular, we show that pure weakly entangled states of two qubits cannot be simulated with one bit of communication. Finally, we discuss the feasibility of experiments in the light of these results.

General approach. Let us consider a typical Bell test scenario. Two distant observers, Alice and Bob, share some quantum state \( \rho_{AB} \). Each of them chooses randomly between a set of measurements (settings) \( \{A_i\}_{i=1..N_A} \) for Alice, \( \{B_j\}_{j=1..N_B} \) for Bob. The result of the measurement is noted \( a, b \). Here we will focus on dichotomic observables (corresponding to Von Neumann measurements on qubits) and Alice and Bob will use the same number of settings, i.e. \( a, b \in \{0,1\} \) and \( N_A = N_B = N \). Repeating the experiment many times, the two parties can determine the joint probabilities \( p(a,b|A_i, B_j) \) for any pairs of settings, as well as marginal probabilities \( p(a|A_i) \) and \( p(b|B_j) \). A Bell inequality is a constraint on those probabilities, which is satisfied for all lhw models. We say that a quantum state is non-local if and only if there are measurement settings such that a Bell inequality is violated. Mathematically speaking a Bell inequality is a polynomial of joint and marginal probabilities. In the case \( N = 2 \) the only relevant Bell inequality is the CHSH inequality, which is defined here using the Clauser-Horne polynomial...
\[ I_{CHSH} = P(A_1B_1) + P(A_1B_2) + P(A_2B_1) - P(A_2B_2) - P(A_1) - P(B_1), \]

where \( P(A,B) \) is a shortcut for \( P(00|A,B) \), the probability that \( a = b = 0 \). The bound for lhv models is \( I_{CHSH} \leq 0 \), while quantum mechanics can reach up to \( I_{CHSH} = \frac{1}{\sqrt{2}} - \frac{3}{2} \).

We also introduce the Bell polynomial

\[ I_{3322} = P(A_1B_1) + P(A_1B_2) + P(A_1B_3) + P(A_2B_1) + P(A_2B_2) + P(A_3B_1) - 2P(A_1) - P(A_2) - P(B_1), \]

which is the only relevant Bell inequality for the case \( N = 3 \) [7]. The local limit is \( I_{3322} \leq 0 \) and quantum mechanics violates \( I_{3322} \) up to \( \frac{1}{\sqrt{2}} - \frac{3}{2} \).

As an introductory example, consider the case where Alice and Bob share maximally entangled states and detect their particles with the same limited efficiency \( \eta \); since they must always produce an outcome, they agree to output "00" in case of no detection. When both detectors fire, \( I_{CHSH} \equiv Q = \frac{1}{\sqrt{2}} - \frac{3}{4}. \) When only Alice’s detector fires, \( P(A_1B_2) = P(A_1) = \frac{1}{4} \) while \( P(B_1) = 1 \), therefore \( I_{CHSH} \equiv M_A = \frac{1}{\sqrt{2}} \); similarly, when only Bob’s detector fires \( I_{CHSH} \equiv M_B = \frac{1}{\sqrt{2}} \). When no detector fires, the lhv bound is reached, \( I_{CHSH} = 0 \). Consequently, the whole set of data violates the CHSH inequality if and only if \( \eta^2Q + \eta(1 - \eta)(M_A + M_B) \geq 0 \) yielding the well-known threshold efficiency \( \eta \geq 82.84\% \).

In general, Alice and Bob test an inequality \( I \leq L \) on a state \( \rho_{AB} \) having two different detection efficiencies, \( \eta_A \) and \( \eta_B \). In analogy to the previous example, Alice and Bob must choose the measurement settings \{\( A_i, B_j \)\} and the local strategy for the case of no detection, in order to maximize

\[ I_{\eta_A \eta_B} = \eta_A \eta_B Q + \eta_A \eta_B M_A + \eta_A \eta_B M_B + \eta_A \eta_B X, \]

where \( \bar{\eta} = 1 - \eta \), \( Q = Tr(B(I)\rho_{AB}) \) is the mean value of the Bell operator \( B(I) \) associated to the inequality, \( M_{A,B} \) and \( X \) are the values of \( I \) obtained from the measurements and the local strategies when one or both detectors don’t fire. We stress that the measurement settings that maximize \( I_{\eta_A \eta_B} \) are not those that maximize \( Q \) for the same quantum state, except for the maximally entangled state. Also, it seems intuitively clear that the optimal local strategies are such that \( X = L \), though we have no general proof of this.

*Case study:* \( \eta_A = 1 \). The general approach above can be carried out for any specific values of the efficiencies; now we consider the limit where Alice’s detector is perfect, \( \eta_A = 1 \). Moreover, we consider inequalities such that \( L = 0 \). From [3] one obtains immediately that the efficiency of Bob’s detector must be above the threshold

\[ \eta_B > \eta_B^t = \frac{1}{1 - Q/M_A} \]

in order to close the detection loophole. For any given state, the measurement settings and Bob’s local strategy in case of no detection must be chosen as to maximize \( |Q/M_A| \) (note that, if \( L = 0 \), \( M_A \leq 0 \)).

Consider first pure states. For the maximally entangled state, one obtains \( \eta_B^t = \frac{1}{\sqrt{2}} \approx 70.7\% \) for the CHSH inequality (the optimal strategy is the same as above) and \( \eta_B^t = \frac{3}{5} \approx 66.7\% \) for the \( I_{3322} \) inequality (the settings are those that achieve \( Q = \frac{1}{2} \), and in the absence of detection Bob outputs leading to \( M_A \approx -\frac{1}{2} \)). Note that a lhv model is known, which reproduces the correlations of the maximally entangled state under the assumption \( \eta_A = 1 \) and \( \eta_B = 50\% \) [19]; it is an interesting open question to close this gap by finding either a better Bell-type inequality, or a better lhv model. For pure non-maximally entangled states, we considered a numerical minimization of \( \eta_B^t \); we find that \( \eta_B^t \) decreases with decreasing \( \theta \), as shown in Fig. [1] (thick lines), in analogy with Eberhard’s result [11]. The optimal settings can always be chosen to lie in the \((x,z)\) plane of the Bloch sphere. In the limit of weakly entangled states, one finds \( \eta_B^t \rightarrow 50\% \) for CHSH and \( \eta_B^t \rightarrow 43\% \) for \( I_{3322} \). It is remarkable that the detection loophole can in principle be closed with \( \eta_B \leq 50\% \); we derive below some consequences for the simulation of entanglement with communication.

We have seen that \( \eta_B^t \) decreases with the degree of entanglement for pure states. However, the violation of the inequality decreases as well. It is therefore important to study the effect of noise. We consider two models of noise. The first is background noise as in Ref. [11]: Alice and Bob share a state of the form

\[ \rho_{AB} = (1 - p)|\psi_0\rangle\langle \psi_0| + p\frac{I}{4}. \]

For \( \theta = \frac{\pi}{4} \), the state [5] is the Werner state. The threshold efficiency as a function of \( \theta \) is shown in Fig. [1] (thin full lines). In Fig. [2] one sees that the \( I_{3322} \) inequality can tolerate lower efficiencies than the CHSH inequality for \( p \leq 6\% \).

Another noise model, probably more relevant for experiments, supposes that Alice’s and Bob’s detectors have a certain probability of error, \( \epsilon_d^A \) and \( \epsilon_d^B \), e.g. due to dark counts in the case of photon detection. The statistics are then described by the state

\[ \rho_{AB} = (1 - \epsilon_d^A)(1 - \epsilon_d^B)|\psi_0\rangle\langle \psi_0| + \epsilon_d^A\frac{I}{2} + \epsilon_d^B\frac{I}{4} + \epsilon_d^A\epsilon_d^B\frac{I}{4}, \]

where \( \rho_A = Tr_B|\psi_0\rangle\langle \psi_0| \) and \( \rho_B = Tr_A|\psi_0\rangle\langle \psi_0| \) are the reduced states of Alice and Bob. In the recent atom-photon experiment done in Munich [14], the atom measurement has \( \eta_A \approx 1 \) and \( \epsilon_d^A \approx 5\% \), whereas the photon measurement is much less efficient but also less noisy. In the light of this, we focus for definiteness on the case \( \eta_A = 1 \) and \( \epsilon_d^B = 0 \). Again, the computed threshold efficiency as a function of \( \theta \) is shown in Fig. [1] (thin dashed lines). We have also found that \( I_{3322} \) can tolerate higher error rates than CHSH as soon as \( \eta_B < 75\% \).

*Connection with the simulation of entanglement.* There is a natural equivalence between lhv models exploiting the
detection loophole in the asymmetric scenario (DL-models) and communication models (C-models) for the simulation of quantum correlations [20, 21]. In a C-model, Alice and Bob share lhv $\lambda'$ where $\lambda'$ is chosen among the possible values of $\lambda$. Alice outputs $a = a(A, \lambda, \eta)$. Bob computes the information $c = c(B, \lambda)$ he should have sent: if $c = d$, he outputs $b = b(B, \lambda)$; otherwise, he does not output anything. Therefore we have a DL-model with $\eta_A = 1$ and $\eta_B = P(c = d)$ [22]. This correspondence applies in particular to the simulation of the singlet [20]: the C-model of Toner and Bacon [23], where $c$ is a randomly distributed bit, translates into the DL-model of Gisin and Gisin [19], where $\eta_A = 1$ and $\eta_B = 0.5$. We derive here two more corollaries.

First, it is known that any state of two qubits can be simulated by a C-model with two bits [23, 24]. Thus one can construct a DL-model with $\eta_A = 1$ and $\eta_B = 0.25$ for all two-qubit state by choosing $P(d = 01) = 0.25$ for any two-qubit state. Second, one cannot simulate with a single bit of communication any state for which the detection loophole can be closed with $\eta_A = 1$ and $\eta_B < 0.5$. In fact, suppose that a C-model with a single bit exists: whatever the statistics of $(c(B, \lambda))$ are, the choice $P(d = 1) = 0.25$ for any two-qubit state gives a DL-model with $\eta_A = 1$ and $\eta_B = 0.5$. Applied to our analysis of the $I_{3322}$ Inequality, this implies that non-maximally entangled states with $\theta \lesssim 0.106\pi$ require more than one bit of communication to be simulated. This last result nicely fits in a series of recent works which suggest that entanglement and non-locality are different resources [25].

Experimental feasibility. Atom-photon entanglement has been demonstrated both with Cd ions in an asymmetric quadrupole trap [14, 15] and with Rb atoms in an optical dipole trap [13]. Non-maximally entangled atom-photon states were already created in Ref. [15]. The overall photon detection efficiency is very low in these experiments, mostly due to inefficient photon collection. The collection efficiency could be brought to the required level by placing the atom inside a high-finesse cavity. For example, Ref. [26] demonstrated coupling of a trapped ion to a high-finesse cavity and achieved $\beta = 0.51$, where $\beta$ is the fraction of spontaneously emitted photons that are emitted into the cavity mode. The experimental conditions in Ref. [27] correspond to $\beta$ very close to 1. Of course, in real experiments there are other sources of loss, such as propagation losses and detector inefficiency. Nevertheless the perspective for closing the detection loophole for two well-separated systems seems excellent using atom-photon implementations.

Performing a loophole-free Bell experiment requires enforcing locality of the measurements [45] in addition to closing the detection loophole. The measurement of the atomic state, which is typically based on detecting fluorescence from a cycling transition, is relatively slow. As a consequence, enforcing locality in an experiment with atom-photon pairs requires a large separation between the two detection stations for the atom and the photon. For example, Ref. [12] estimated that for trapped Ca ions the atomic measurement could be performed in $30 \mu$s, assuming that 2% of the photons from
the cycling transition are collected, leading to a required separation of 10 km. Obviously such large distances make high-efficiency detection of the photon more difficult. In Ref. [14] the authors suggest that it may be enough for the state of the atom to have collapsed, rather than for the result of the measurement to have been recorded, which leads them to a smaller required separation of 150 m. However, from the strict perspective of testing the most general hidden variable models this assumption is somewhat unsatisfactory.

A more promising alternative for an asymmetric loophole-free Bell experiment may be a purely optical implementation, using a source of entangled photon pairs such as parametric down-conversion. One photon from the source impinges directly on a highly efficient detector [28, 29], while the second photon is sent over a long distance, leading to a lower efficiency $\eta_B$. For $\eta_A = 90\%$, $\varepsilon_d^A = \varepsilon_d^B = 10^{-3}$, we find $\eta_B^{th} \approx 60\%$ (with $\theta \approx 0.05\pi$). Since photon detection can be much faster than the atomic detection (of order of ns), the required distance for a loophole-free experiment can be much shorter, making it easier to achieve relatively high $\eta_B$.

**Conclusions and Outlook.** We discussed the detection loophole in asymmetric Bell tests. We showed that, for the inequality $I_{3322}$, a minimal detection efficiency of $\eta_B = 43\%$ can be tolerated (for $\eta_A = 1$), considering non-maximally entangled states. Based on connections with the problem of simulating quantum correlations, we derived a lower bound for the threshold efficiency, $\eta_B^{th} > 25\%$ for two-qubit states. It is an interesting question whether this bound can be reached by considering other Bell inequalities. Furthermore we proved that a single bit of communication is not enough to simulate the correlations of certain non-maximally entangled states of two qubits. From an experimental point of view, we have argued that atom-photon entanglement seems promising for closing the detection loophole for well separated systems. Moreover asymmetric Bell experiments with photon pairs open up a new possibility for a loophole free Bell test.

**Note added in proof.** While finishing the writing of this manuscript, we became aware that the results presented here about the CHSH inequality were independently derived by Cabello and Larsson [30].
