ABSTRACT

We present the first results using the Reuven Ramaty High-Energy Solar Spectroscopic Imager, RHESSI, to observe solar X-ray emission not associated with active regions, sunspots or flares (the quiet Sun). Using a newly developed chopping technique (fan-beam modulation) during seven periods of off-pointing between June 2005 to October 2006, we obtained upper limits over 3-200 keV for the quietest times when the GOES12 1-8 Å flux fell below 10^{-8} Wm^{-2}. These values are smaller than previous limits in the 17-120 keV range and extend them to both lower and higher energies. The limit in 3-6 keV is consistent with a coronal temperature \leq 6 MK. For quiet Sun periods when the GOES12 1-8 Å background flux was between 10^{-8} Wm^{-2} and 10^{-7} Wm^{-2}, the RHESSI 3-6 keV flux correlates to this as a power-law, with an index of 1.08 \pm 0.13. The power-law correlation for microflares has a steeper index of 1.29 \pm 0.06. We also discuss the possibility of observing quiet Sun X-rays due to solar axions and use the RHESSI quiet Sun limits to estimate the axion-to-photon coupling constant for two different axion emission scenarios.

Subject headings: Sun: X-rays, gamma rays – Sun: activity – Sun: corona – elementary particles

1. INTRODUCTION

The X-ray spectrum of the Sun free of sunspots, active regions and flares (the quiet Sun) is an important yet elusive measurement, despite interest back to the earliest days of solar X-ray observations (e.g., Neupert 1969). Such an observation would provide insight into the nature of possible small-scale steady-state energisation processes in the solar corona. For soft X-rays (i.e., X-rays emitted by thermal sources as free-free, free-bound continua or lines) the solar corona is comparable to other stars (e.g., Pevtsov & Acton 2001). The stellar coronal emission consists of contributions from more than one physical component with an emission measure distributed over temperature. For hard X-rays (usually characterised by an arbitrary minimum photon energy instead of defined as non-thermal bremsstrahlung) there is only one reported observation, that of Peterson et al. (1966).

Observations of soft X-ray emission not associated with active regions, for instance with Yohkoh/SXT (Harvey et al. 1992), show X-ray bright points that are weak compared to active region emission. They are numerous, well-dispersed across the solar disk and are associated with network boundaries. The presence of non-thermal electrons in these events has been inferred from radio observations (Krucker et al. 1997) but no hard X-ray emission was detected. This is because previous hard X-ray imaging observations (Solar Maximum Mission/HXIS, Hinotori, and Yohkoh/HXT) were optimized to study flares, and were ill-suited to observe weak sources distributed over large angular scales.

With small flares, i.e. microflares, the presence of non-thermal electrons has been confirmed by microwave (Gary et al. 1997) and RHESSI hard X-ray observations (Krucker et al. 2002). Imaged RHESSI microflares are always associated with active regions (Hannah et al. 2006). Although we might expect hard X-ray emission from below the current limit of microflare observability, it is uncertain whether such a population would exist in the absence of active regions. It is speculated that smaller non-thermal energy releases, such as “nanofores” (Parker 1988), could produce globally distributed hard X-rays.

In addition to these processes, the interaction of cosmic rays in the solar atmosphere could also generate weak diffuse X-rays from the quiet Sun (Dolan & Fazio 1965; Seckel et al. 1991). Additional nuclear processes arising from such cosmic ray interactions are likely to only produce minuscule X-ray emission: for instance inner bremsstrahlung from \beta-decaying neutrons in the solar analog of the “CRAND” (Cosmic-Ray Albedo Neutron Decay) mechanism (MacKinnon 2007), is predicted to produce X-rays at a level far below that of the diffuse cosmic background, which is 10^{-4} to 10^{-8} ph s^{-1} cm^{-2} keV^{-1} from 3 keV to 100 keV over a solar disk area.

Axions (Weinberg 1978; Wilczek 1978) are hypothetical weakly-interacting particles that could also produce an X-ray signature from the Sun (Sikivie 1983). Nuclear reactions in stellar cores should produce axions copiously; in the case of the Sun the average energy of
axions is 4.2 keV \cite{vanBibber1989}. These axions can convert directly to X-ray photons in a perpendicular magnetic field \cite{Sikivie1983}, with the resulting photons having the same energy and momentum as the incident axion. Ground-based experiments using strong magnetic fields have tried to use this process to search for solar axions \cite{Zioutas2005}. The probability of this conversion is proportional to the square of the product of the axion-photon coupling, the distance travelled through a perpendicular magnetic field, and the strength of this field \cite{Sikivie1983}. This raises the possibility of conversion in the corona \cite{Carlson1996}. Attempting to observe such a small flux would be difficult but would be more favourable during quiet Sun periods when the conventional X-ray emission from the Sun is at a minimum.

The Reuven Ramaty High-Energy Solar Spectroscopic Imager, \textit{RHESSI} \cite{Lin2002}, has unprecedented sensitivity for 3-25 keV X-rays because when its automated attenuators are “out” it can observe with the full area its detectors. This was not possible for earlier instruments which used fixed shielding to prevent excessive counting rates from soft X-rays in flares. Normal \textit{RHESSI} imaging is accomplished with a set of nine bi-grid rotating modulation collimators (RMCs) with resolutions logarithmically spaced from 2.3 to 183 arcseconds. Each RMC time-modulates sources whose size scale is smaller than their resolution. Thus despite its sensitivity, \textit{RHESSI} is not well suited to observe weak sources larger than ~ 3 arcminutes. Most potential mechanisms for quiet-Sun emission would be expected to be weak and well-dispersed across the 32 arcminute solar disk.

For weak sources it is essential to distinguish counts due to solar photons from counts due to terrestrial, cosmic or instrumental background. We adopt an offpointing technique called \textit{fan-beam modulation} \cite{Hannah2007}, that provides a time-modulated, or “chopped”, signal of the solar disk, allowing us to distinguish distributed solar emission from the background.

In this letter we detail the first analysis of periods of quiet Sun with \textit{RHESSI} using the fan-beam modulation technique \cite{Lin2007}. We present the first limits of the quiet Sun X-ray spectrum and show how this correlates with \textit{GOES} 1-8 Å flux and \textit{RHESSI} microflares in \ref{sec:fan-beam}. In \ref{sec:fan-beam} we discuss the X-ray emission due to solar axions and in \ref{sec:fan-beam} we discuss the further work that can be achieved using fan-beam modulation during solar minimum conditions.

\section{Fan-beam modulation technique}

Instead of using the rapid time modulation associated with its RMCs, \textit{fan-beam modulation} is based on a secondary modulation that results from the finite thickness of \textit{RHESSI}’s collimator grids \cite{Hurford2002}. Fan-beam modulation depends upon the offpointing angle, with a maximum effect when \textit{RHESSI} is between 0.4° and 1° from offpointed Sun center \cite{Hannah2007}. This “envelope” modulation peaks twice every rotation when the slits of the grids are parallel to the line between \textit{RHESSI} pointing and source center, producing two transmission maxima per rotation. For a period of offpointing we bin (or “stack”) the data in a chosen energy range according to the roll angle of the spacecraft.

\begin{table}[h]
\centering
\caption{The weighted mean, and its associated standard deviation, of quiet Sun photon flux for periods when \textit{GOES} 1-8 Å flux $< 10^{-8}$ Wm$^{-2}$.}
\begin{tabular}{cccc}
\hline
Energy & Weighted Mean & $\sigma$ & \\
keV & $\times 10^{-8}$ph s$^{-1}$ cm$^{-2}$ & keV$^{-1}$ & \\
\hline
3–6 & 330.99 & ±207.25 & \\
6–12 & -5.24 & ±8.46 & \\
12–25 & -0.73 & ±1.34 & \\
25–50 & 0.14 & ±0.63 & \\
50–100 & 0.74 & ±0.54 & \\
100–200 & -0.79 & ±0.42 & \\
\hline
\end{tabular}
\end{table}

These data are fitted with the expected modulation and the resulting amplitude is corrected for the predicted grid transmission efficiency. This technique works best in \textit{RHESSI}’s RMC with the narrowest field of view, RMCs 1 to 6. In addition, RMCs 2, 5 and 7 are not used in this analysis as they have the poorest energy response.

This type of observation has been done for a total of 45 days during seven periods (2005 July 19-26, 2005 October 18-28, 2006 January 12-17, 2006 February 1-7, 2006 August 3-8, 2006 September 26-29 and 2006 October 12-23), when the \textit{GOES} 1-8 Å flux was around $10^{-8}$ Wm$^{-2}$ and no active regions or spots were on the disk. The Sun was very quiet during these periods with the microwave emission (F10.7 levels) in the range 70–78 SFU and the \textit{GOES} 1-8 Å flux “flat-lining” below $10^{-8}$ Wm$^{-2}$, the equivalent of an A1 class flare.

The data set was divided into five-minute time intervals, which are short enough so that the radial offset, and hence grid transmission factor, changes little. For the quiet Sun results presented in this paper we have removed intervals with sharp time-series features (such as flares or particle events). The analysis was further restricted to times when \textit{RHESSI} is at the lowest latitudes in its orbit, to minimize the terrestrial background. From these four offpointing periods we have a total of 1,774 five-minute time intervals (over 147 hours of data), 1,071 in its orbit, to minimize the terrestrial background. From these four offpointing periods we have a total of 1,774 five-minute time intervals (over 147 hours of data), 1,071 (or 89.25 hours) of which occurred while the \textit{GOES} 1-8 Å flux was below the A1 class of $10^{-8}$ Wm$^{-2}$. For each of these time intervals, and over chosen energy bands, we have an amplitude of the quiet Sun count rate corrected for the transmission through \textit{RHESSI}’s grids. The resulting fitted amplitudes are then combined from different time intervals to improve the signal to noise before conversion to a final photon flux using the diagonal elements of the appropriate detector response matrix \cite{Smith2002}.

\section{RHESSI quiet Sun spectrum}

Figure \ref{fig:energy} shows the average 3-6 keV emission for six of \textit{RHESSI}’s detectors. There is a small scatter between the detectors, but consistent to within the errors. To calculate the average overall flux for each energy band, we use the weighted mean of the value found in RMCs 1, 3, 4 and 6, and give the error as the standard deviation in this weighted mean. Table \ref{tab:energy} shows these values for energy bands between 3 to 200 keV during the quietest times.

None of the values given in Table \ref{tab:energy} show a clear sta-
We can gain a better understanding of possible quiet Sun X-ray emission by using the errors given in Table I shown in Figure 2. The dotted histogram shows the data of Peterson et al. (1966), who made pioneering solar hard X-ray observations with balloon-borne scintillation counters, in the 17 to 120 keV range. Our hard X-ray upper limits improve upon these results to about 75 keV and are above this energy. Our results also extend the energy range into the previously unmeasured domains below 17 keV and above 120 keV.

Figure 2 also shows four CHIANTI thermal spectral models for coronal emission (Dere et al. 1997; Landi & Phillips 2006). For each assumed temperature the emission measure is constrained by Landi & Phillips (2006). For each assumed temperature the emission measure is constrained by Yohkoh/SXT observations, which was sensitive to 1-2 keV X-rays, during solar minimum (Pevtsov & Acton 2001). The RHESSI limit in 3-6 keV is consistent with a quiet coronal temperature $\leq 6$ MK.

We can gain a better understanding of possible quiet Sun X-ray emission by using all 1,774 five-minute time intervals, not just the quietest periods. These quiet Sun observations occurred over a range of GOES12 1-8 Å background fluxes up to $10^{-7}$ Wm$^{-2}$ an still in the absence of active regions. By calculating the RHESSI flux in consecutive subsets of GOES12 background fluxes, we can plot the correlation of RHESSI quiet Sun 3-6 keV flux to GOES12, shown by the broad crosses in Figure 3. The errors shown here are the statistical ones found from the fit errors from each time interval combined in quadrature. There is a clear power-law correlation between the GOES12 and RHESSI data, with an index of $\gamma = 1.08 \pm 0.13$.

To put these observations in context we have also shown, as the square data points in Figure 3, the fluxes for eight microflares that occurred during quiet Sun off-pointing. The times of these microflares were excluded from our quiet Sun 5 minute time intervals, since they are a sign of activity. We used the fan-beam modulation technique for 16 seconds about the peak of these flares and plotted the flux against the corresponding
Fig. 3.— The 3-6 keV photon flux from the fan-beam modulation technique for the quiet Sun (broad crosses) and eight microflares during offpointing (square data points) as compared to the corresponding 1-8 Å GOES12 flux. The GOES12 flux for the microflares is background subtracted. The fitted line for the quiet Sun points uses the five data points above GOES12 A1 class; below this level the GOES12 data digits as it reaches its sensitivity limit.

smaller than the value cited by Zioutas et al. (2004); and repeating their calculation, we find a somewhat smaller limit to the axion-photon coupling constant within this scenario of $g_{a\gamma\gamma} \lesssim 6 \times 10^{-15}$ GeV$^{-1}$.

5. DISCUSSION & CONCLUSIONS

We have established new upper limits on quiet-Sun emission in hard X-rays when activity levels were below GOES12 A1 class. The most natural explanation of such possible emission is that of unresolved microflares. Figure 3, however, indicates that such emission would require an ensemble of very small microflares, as the RHESSI flux for resolved microflares is over two orders larger than that of the quiet Sun. In this regime the energy release may be due to a mechanism physically different from (micro-) flares, such as the speculated nano-flares (Parker 1988). These quiet Sun limits must be interpreted in terms of our knowledge of the distribution function of flare magnitudes, which follows a flat power law (Hudson 1991). The comparisons in Figure 3 would then yield a normalisation of the distribution law (e.g., the constant multiplier in the power-law distribution). This will be calculated once the RHESSI microflare distribution is known—such a study is near completion (Hannah et al. 2006).

The work presented here represents the first use of the fan-beam modulation technique and shows that this method opens a new regime of observations for RHESSI, namely weak sources larger than 3 arcminutes in size. Further use of this technique during the quieter times of solar minimum should help improve the limits presented here.

The detection of the component of the solar X-ray flux due to axions converting in the coronal magnetic field is especially challenging. Carlson & Tseng (1996) suggested that the stronger magnetic fields associated with sunspots should permit tighter limits and are valid up to higher values of the axion mass. However such limits would be subject to greater uncertainties associated with the modeling of these magnetic fields. Using RHESSI to search for this emission due to axions may be more effective despite the large background from conventional emission since we know the characteristic spatial scale (i.e., core size) on which the emission is expected to occur (van Bibber et al. 1989) and it should vary in a distinctive manner as the sunspot moves across the solar disk. Given RHESSI’s low Earth orbit, it may be preferable to observe the X-rays produced through the conversion of axions in Earth’s nightside magnetic field (Davoudiasl & Huber 2003). This method has the advantage that the Earth blocks the competing solar X-ray flux.

A detailed presentation of RHESSI limits on solar axions from both daytime and nighttime observations of the Sun will be the subject of a subsequent paper.

6. ACKNOWLEDGEMENTS

NASA supported this work under grant NAG5-9803. Work at Lawrence Livermore National Laboratory was supported under Department of Energy Contract W-7405-Eng-048. We thank many people involved in the RHESSI program for inspiration and assistance with software, calibration, and spectral fitting issues, especially Brian Dennis, Richard Schwartz and David Smith.
