The Multiplicative Quantum Adversary

Robert Špalek
spalek@eecs.berkeley.edu

Abstract

We present a new variant of the quantum adversary method. All adversary methods give lower bounds on the quantum query complexity of a function by bounding the change of a progress function caused by one query. All previous variants upper-bound the difference of the progress function, whereas our new variant upper-bounds the ratio and that is why we coin it the multiplicative adversary. The new method generalizes to all functions the new quantum lower-bound method by Ambainis [Amb05, ASW06] based on the analysis of eigenspaces of the density matrix. We prove a strong direct product theorem for all functions that have a multiplicative adversary lower bound.

1 Introduction

We consider the problem of proving a lower bound on the number of quantum queries needed to compute a function with bounded error. One of the most successful methods for proving quantum query lower bounds is the adversary method [BBBV97, Amb02, HNS02, BS04, BSS03, Amb03, LM04, Zha05, SS06, HLS06]; see the survey [HS05] for the history of the method. It intuitively works as follows: The computation starts in a fixed quantum state independent of the input. The quantum algorithm consecutively applies arbitrary unitary transformations on its workspace and the input oracle operator. The quantum state corresponding to two different inputs $x, y$ gradually diverges to two output states $|\psi^T_x\rangle, |\psi^T_y\rangle$. Since the algorithm has bounded error, there exists a measurement on the output state that gives the right outcome with high probability, hence the scalar product $|\langle \psi^T_x | \psi^T_y \rangle|$ must be low whenever $f(x) \neq f(y)$ [BV97]. We define a progress function in time $t$ as a weighted average of these scalar products over many input pairs:

$$W^t = \sum_{x,y} w_{x,y} |\langle \psi^t_x | \psi^t_y \rangle|.$$  

(1)

Since the scalar products are all one at the beginning and below a constant at the end, the value of the progress function must drop a lot. On the other hand, one can show that one query only causes little additive change to the progress function, hence the algorithm must ask many queries. The quality of the lower bound depends on the adversary matrix $w$—one typically has to put more weight on input pairs that are hard to distinguish to get a good bound.

The progress function can be equivalently formulated in terms of density matrices. If we run the quantum algorithm on a superposition of inputs instead of a fixed input, then during the computation the algorithm register becomes entangled with the input register. We trace out the algorithm register and look at the reduced density matrix $\rho_I$ of the input register. We define the progress function as a linear form

$$W^t = \langle \Gamma, \rho_I \rangle.$$  

(2)

for some Hermitian matrix $\Gamma$ with $\Gamma[x,y] = 0$ if $f(x) = f(y)$. This definition is equivalent with Eqn. (1) (see Section 2 for a proper definition), and since it is easier to work with, we will stick to it in the whole paper.

*University of California, Berkeley. Supported by NSF Grant CCF-0524837 and ARO Grant DAAD 19-03-1-0082.
The (additive) adversary method suffers one severe limitation: the lower bound is proportional to the success probability of the algorithm and hence is negligible for exponentially small success probabilities. Several many-output functions, such as $t$-fold search, however, have strong lower bounds even with exponentially small success [KSW07] (proved first using the polynomial method [BBC+01]). These bounds are useful for proving quantum time-space tradeoffs.

Ambainis reproved [Amb05] and extended [ASW06] these polynomial lower bounds using a new quantum lower-bound method based on the analysis of subspaces of the reduced density matrix of the input register. His method seemed tailored to the problem of quantum search, and is quite complicated.

In this paper, we reformulate Ambainis’s new method in the adversary framework, generalize it to all functions, and provide some additional intuition. We use syntactically the same progress function Eqn. (2), but in a different way: (1) we require different conditions on the adversary matrix $\Gamma$, and (2) we show that one query can only multiply the value of the progress function by a small constant—thereout the name multiplicative adversary. Surprisingly, the final formula for the multiplicative adversary lower bound is quite similar to the additive adversary. Unfortunately, the similarity is only illusive, and our new formula is significantly harder to bound than the old one and we thus don’t simplify Ambainis’s calculations much.

We, however, split Ambainis’s original proof into several independent logical blocks and dovetail them together: upper-bounding the success probability based on the structure of the subspaces, upper-bounding the change caused by one query, simultaneous block-diagonalization of $\Gamma$ and the query operator, and simplification of the final formula into a form similar to the additive adversary. This simplification allows us to generalize the method to all functions. Furthermore, we separate the quantum part and the combinatorial part of the proof—the quantum part is hidden inside the proof of the general lower-bound theorem (Section 3), and the user of the method who wants to get a lower bound for some function only has to evaluate its combinatorial properties (see Section 4 for new proofs of all known bounds in our new framework).

Finally, we show that the multiplicative adversary bound inherently satisfies the strong direct product theorem (DPT). Roughly speaking it says that to compute $k$ independent instances of a function we need $\Omega(k)$ times more queries even if we are willing to decrease the (worst-case) success probability exponentially. It is not clear whether this theorem holds for all functions or not. Ambainis proved a (more complicated) DPT for all symmetric functions directly, whereas we show that it is sufficient to prove just a (simpler) multiplicative adversary lower bound, and the DPT then automatically follows (Section 5).

The biggest open problem, not addressed here, is to find a new stronger lower bound using the multiplicative adversary. A promising function is the element distinctness problem (tight $\Omega(n)$ lower bound due to the polynomial method [AS04], but only $\Omega(\sqrt{n})$ adversary lower bound). It also doesn’t seem completely unlikely that one could find a reduction from the additive adversary to the multiplicative adversary—if a lower bound for some function can be proved using one method, then it can be proved also using the other one. If this is true, then many extensive computations could be chucked. The multiplicative adversary method may also have potential to prove a quantum time-space tradeoff for some Boolean function (again, element distinctness), because small workspace implies small Schmidt-rank of the reduced density matrix.

2 Adversary framework

Query oracle Let $f : X \to \Sigma_O$ be a (partial) function on $n$ variables, where $X \subseteq \Sigma_I^n$ is the set of inputs, $\Sigma_I = \{0, 1, \ldots, \sigma - 1\}$ is the input alphabet, and $\Sigma_O$ is the output alphabet. If $\sigma = 2$, we say that $f$ is a Boolean function. We measure the complexity of $f$ in the number of queries required to compute $f$ with high probability. On an input string $x \in X$, one query maps

$$|i, p\rangle |w\rangle \xrightarrow{O_x} e^{\frac{2\pi ipx}{\sigma}} |i, p\rangle |w\rangle,$$

where $i \in [n]$ is the index of the queried input variable, $p \in \Sigma_I$ is the phase multiplier, and $w$ is an arbitrary register untouched by the query. For a Boolean function, the query operator maps $|i, p\rangle \mapsto (-1)^{px} |i, p\rangle$. This query operator $O_x$ that encodes the result in the quantum phase is equivalent to the operator $O_x' : |i, p\rangle \mapsto |i, (x_i + p) \mod \sigma\rangle$ that stores the result in a register—by conjugating with the quantum Fourier transform. The phase encoding is more suitable for proving lower bounds.
**State of computation**  Denote the quantum state on input $x$ after $t$ queries by

$$|\psi_t^x\rangle = \sum_{i=1}^{n} \sum_{p=0}^{\sigma-1} |i, p\rangle |\psi_{x,i,p}^t\rangle,$$

where $|\psi_{x,i,p}^t\rangle$ is not normalized. If we run computation on a superposition of inputs $|\delta\rangle = \sum_{x \in X} \delta_x |x\rangle$, then the quantum state after $t$ queries is

$$|\psi^t\rangle = \sum_x \delta_x |x\rangle |\psi^t_x\rangle = \sum_x \delta_x |x\rangle |\sum_{i,p} |i, p\rangle |\psi_{x,i,p}^t\rangle_A.$$

where $I$ is the input register, $Q$ is the query register, and $A$ is the algorithm register. The reduced density matrix of the input and query register is

$$\rho_{I,Q}^t = \text{Tr}_{I,Q} |\psi^t\rangle \langle \psi^t| = \sum_{x,y} \delta_x \delta_y^* \langle x| \sum_{i,j,p,q} |i,p\rangle \langle j,q| : \langle \psi_{y,j,q}^t| \psi_{x,i,p}^t\rangle_A.$$

The reduced density matrix of the input register alone is

$$\rho_I^t = \text{Tr}_Q |\psi^t\rangle \langle \psi^t| = \sum_{x,y} \delta_x \delta_y^* \langle x| \sum_{i,p} |i,p\rangle \langle \psi_{x,i,p}^t|$$

$$= \sum_{x,y} \delta_x \delta_y^* |\psi_{x,i,p}^t\rangle : |x\rangle \langle y|.$$

**Progress function**  We define a progress function in terms of the reduced density matrix of the input register and an adversary matrix $\Gamma$. We present two kinds of adversary method, each using the progress function in a different way to get a quantum query lower bound.

**Definition 1**  Let $\Gamma$ be an $|X| \times |X|$ Hermitian matrix. Let $\langle A, B \rangle = \text{Tr}(A^* B)$. Define the following progress function

$$W^t = \langle \Gamma, \rho_I^t \rangle = \langle G, \rho_{I,Q}^t \rangle$$

with $G = \Gamma \otimes I_n \otimes I_\sigma = \bigoplus_{i=1}^{n} \bigoplus_{p=0}^{\sigma-1} \Gamma$.

Note that $W^t$ is a real number, because both $\Gamma$ and $\rho_I^t$ are Hermitian.

**Definition 2**  Define also the following set of $|X| \times |X|$ Hermitian matrices and one larger composite block-diagonal matrix:

$$D_i[x, y] = \begin{cases} 1 & x_i \neq y_i \\ 0 & x_i = y_i \end{cases} \quad D = \bigoplus_{i,p} D_i.$$  Define the following set of $|X| \times |X|$ diagonal unitary matrices and one larger composite diagonal unitary:

$$Z_{i,p}[x, x] = e^{2\pi i px_i} \quad Z = \bigoplus_{i,p} Z_{i,p}.$$  Finally, define the following complete set of diagonal orthogonal projectors $\{F_z\}_{z \in \Sigma_O}$, and one Hermitian matrix:

$$F_z[x, x] = \begin{cases} 1 & f(x) = z \\ 0 & f(x) \neq z \end{cases} \quad F[x, y] = \begin{cases} 1 & f(x) \neq f(y) \\ 0 & f(x) = f(y) \end{cases},$$

that is $\sum_z F_z = I$, $F_{z_1} F_{z_2} = 0$ for $z_1 \neq z_2$, and $F_z^2 = F_z$. 

3
2.1 Additive adversary

In this version of the adversary method, one upper-bounds the difference of the value of the progress function caused by one query. This method is the original adversary method, developed in a series of papers [BBBV97, Amb02, HNS02, BS04, BSS03, Amb03, LM04, Zha05, SS06, HLS06].

**Theorem 1** Let \( \Gamma \) be a nonzero \(|X| \times |X|\) Hermitian matrix such that \( \Gamma[x,y] = 0 \) for \( f(x) = f(y) \), or, equivalently, \( \Gamma = \Gamma \circ F \). Consider a quantum algorithm with error probability at most \( \varepsilon \) and query complexity \( T \). We run it on the superposition of inputs \( |\delta\rangle \), where \( \delta \) is a normalized principal eigenvector of \( \Gamma \), i.e. corresponding to the spectral norm \( \|\Gamma\| \). Then

1. \( W^0 = \|\Gamma\| \)
2. \( |W^{t+1} - W^t| \leq 2 \max_i \|\Gamma \circ D_i\| \) for every time step \( t = 0,1, \ldots, T - 1 \)
3. \( |W^T| \leq 2(\sqrt{\varepsilon(1 - \varepsilon)} + \varepsilon) \cdot \|\Gamma\| \)

The third item can be strengthened to \( 2\sqrt{\varepsilon(1 - \varepsilon)} \|\Gamma\| \) if \( f \) has Boolean output [HLS06]. The proof of the more general non-Boolean statement will soon appear on the arXiv in a revised version of the same paper.

**Corollary 2** ([BSS03, HLS06]) For every sufficiently small \( \varepsilon \),

\[
Q_{\varepsilon}(f) \geq \text{ADV}_{\varepsilon}(f) \overset{\text{def}}{=} \left( \frac{1}{2} - \sqrt{\varepsilon(1 - \varepsilon)} - \varepsilon \right) \max_i \|\Gamma\|_{\max_i \|\Gamma \circ D_i\|}.
\]

If all coefficients of the adversary matrix \( \Gamma \) are nonnegative, then \( \Gamma \) corresponds to a hard distribution over input pairs and its principal eigenvector \( \delta \) to a hard distribution over inputs. The initial value of the progress function \( W \) is large, because all scalar products are one in the beginning, and it must decrease a lot. This is because the weight is only put on input pairs evaluating to different outputs, whose scalar product must be low at the end, otherwise one would not be able to distinguish them. This intuition does not tell the whole truth if some coefficients are negative, but the adversary bound still holds.

3 Multiplicative adversary

In this version of the adversary method, one upper-bounds the ratio of the value of the progress function before and after a query. This method is a simplification and generalization of the new adversary method developed by Ambainis [Amb05, ASW06]. Here, \( \Gamma \) has a different semantics. We require the eigenspaces of \( \Gamma \) corresponding to small eigenvalues to be spanned by vectors (superpositions of inputs) that do not determine the function value with high probability. The algorithm is then run on a superposition \( |\delta\rangle \) corresponding to the smallest eigenvalue (which is typically a uniform superposition of all inputs), and the progress function \( W \) is slowly increasing (instead of decreasing) in time. To achieve good success probability, most of the quantum amplitude must move to the higher subspaces.

**Theorem 3** Let \( \Gamma \) be positive definite with smallest eigenvalue \( 1 \); then \( W^0 \geq 1 \). Fix a number \( 1 < \lambda \leq \|\Gamma\| \).

Let \( \Pi_{\text{bad}} \) be the projector onto the eigenspaces of \( \Gamma \) corresponding to eigenvalues smaller than \( \lambda \). Assume that \( \|F_z \Pi_{\text{bad}}\|^2 \leq \eta \) for every output letter \( z \in \Sigma_O \). Consider a quantum algorithm with success probability at least \( \eta + 4\varepsilon \Gamma \) and query complexity \( T \). We run it on the superposition of inputs \( |\delta\rangle \), where \( \delta \) is a normalized eigenvector of \( \Gamma \) with \( \Gamma \delta = \delta \). Then

1. \( W^0 = 1 \)
2. \( \frac{W^{t+1}}{W^t} \leq \max_i \|\Gamma_{i,p}/\Gamma\| \), where \( \Gamma_{i,p} = Z_{i,p}^* \Gamma Z_{i,p} \) and \( \Gamma_{i,p}/\Gamma \) denotes \( \Gamma_{i,p} \Gamma^{-1} \)
3. \( W^T \geq \zeta^2 \lambda \)
Theorem 3 \[ (1) \]
holds for pure states and consequently also for all density matrices. \[ (2) \]

We conclude that

\[ \text{Proof of Lemma 5} \]

\[ \text{Corollary 6} \]

\[ \text{Proof of Theorem 3 (1)} \]

Trivial, because \( \langle \psi^0 | \psi^0 \rangle = 1 \) and thus \( W^0 = \langle \Gamma, \rho^0 \rangle = \langle \delta | \delta \rangle = 1 \).

\[ \text{Proof of Theorem 3 (2)} \]

Let \( \rho = \rho_{l,q}^1 \) be an arbitrary density matrix and \( \rho' = \rho_{l,q}^{t+1} \) be the density matrix after performing one query. We show that

\[ \langle G, \rho' \rangle \leq \max_{i,p} \| \Gamma_{i,p} / \Gamma \| \cdot \langle G, \rho \rangle. \] (3)

Since the scalar product \( \langle G, \rho \rangle \) is linear in \( \rho \), it suffices to show this inequality for pure states \( \rho = |\psi\rangle \langle \psi| \). Let

\[ |\psi\rangle = \sum_{x,i,p} x_{i,p} |x, i, p\rangle \]

and the value of the progress function after a query is

\[ \langle G, \rho' \rangle = \langle G, Z \rho Z^* \rangle = \langle Z^* G Z, \rho \rangle = \langle G', \rho \rangle, \]

where \( G' = \bigoplus_{i,p} \Gamma_{i,p} \) is a block-diagonal matrix with \( \Gamma_{i,p} \)'s on the main diagonal.

Since both \( \Gamma \) and all \( \Gamma_{i,p} \)'s are positive definite, both \( G \) and \( G' \) are also positive definite. Let

\[ |\tau\rangle = \sqrt{G} |\rho\rangle, \]

that is \( |\rho\rangle = G^{-\frac{1}{2}} |\tau\rangle \).

\[ \frac{\langle G, \rho' \rangle}{\langle G, \rho \rangle} = \frac{\langle G', \rho \rangle}{\langle G, \rho \rangle} = \frac{\langle \rho | G' | \rho \rangle}{\langle \rho | G | \rho \rangle} = \frac{\langle \tau | G^{-\frac{1}{2}} G' G^{-\frac{1}{2}} | \tau \rangle}{\langle \tau | \tau \rangle} = \left( \frac{\| \sqrt{G' / G} |\tau\rangle \|}{\| \tau \|} \right)^2. \]

\[ \leq \| \sqrt{G' / G} \|^2 = \| G' / G \| = \max_{i,p} \| \Gamma_{i,p} / \Gamma \| \]

We conclude that Eqn. (3) holds for pure states and consequently also for all density matrices.

Since the spectral norm of \( \Gamma_{i,p} / \Gamma \) is hard to upper-bound, we simplify it to a form similar to the additive adversary.

Lemma 5 Fix the index of the queried bit \( i \). Assume that \( \Gamma \) and all \( Z_{i,p} \) are simultaneously block-diagonal in some “basis”, that is there exists a complete set of orthogonal projectors \( \Pi = \{ \Pi_\ell \}_\ell \) such that \( \Gamma = \sum_\ell \Gamma_\ell \) and \( Z_{i,p} = \sum_\ell Z_{i,p}^\ell \), where \( \Gamma_\ell \) denotes \( \Pi_\ell \Pi_\ell \). Then

\[ \| \Gamma_{i,p} / \Gamma \| = \max_\ell \| \Gamma_{i,p} / \Gamma_\ell \| \leq 1 + 2 \max_\ell \frac{\| \Gamma_\ell \circ D_i \|}{\lambda_{\min}(\Gamma_\ell^2)} \]

where \( \lambda_{\min}(M) \) denotes the smallest eigenvalue of \( M \).

Corollary 6 Let \( \Gamma \geq I \) and \( 1 < \lambda \leq \| \Gamma \| \). Assume that \( \| F_\ell \Pi_{\text{bad}} \|^2 \leq \eta \) for every \( z \in \Sigma_O \), where \( \Pi_{\text{bad}} \) is the projector onto the eigenspaces of \( \Gamma \) smaller than \( \lambda \). For a fixed \( i \), block-diagonalize simultaneously \( \Gamma \) and all \( Z_{i,p} \), and let \( \Gamma_\ell \) denote the \( \ell \)-th block.

\[ \text{MADV}_{\eta,4\zeta}(f) \geq \max_{\Gamma, \lambda} \log(\zeta^2 \lambda) \cdot \min_{\ell, i} \frac{\lambda_{\min}(\Gamma_\ell^2)}{2 \| \Gamma_\ell \circ D_i \|}. \]
Note that for most functions, one typically does not want to apply this statement using the trivial block-diagonalization \( \Pi = \{ I \} \) with just one projector onto the whole space. In this case, \( \| \Gamma \circ D_i \| \) is way too large compared to \( \lambda_{\min}(\Gamma) \) and the final bound is too weak. For some functions, such as unordered search, however, even this approach gives a reasonable bound; see Lemma 7.

**Proof of Lemma 5** Denote \( Y_{i,p} = Z_{i,p}^* E Z_{i,p} \), where \( E \) is the all-ones matrix; then \( \Gamma_{i,p} = Z_{i,p}^* \Gamma Z_{i,p} = \Gamma \circ Y_{i,p} \).

Note that \( Y_{i,0} - \frac{1}{\mu} \sum_{p=1}^{P} Y_{i,p} = D_i \) (by summing a geometrical sequence depending on \( x_i - y_i \)). Since \( \Gamma \) and all \( Z_{i,p} \) are block-diagonal in \( \Pi \), it follows that \( \Gamma_{i,p}, \Gamma_i / \Gamma \), and \( \Gamma \circ D_i \) are block-diagonal in \( \Pi \), too. Therefore it suffices to compute an upper bound on \( \| \Gamma_{i,p} / \Gamma \| \) in each subspace of \( \Pi \) separately and take the maximum as the total upper bound. This proves the first part of the lemma that \( \| \Gamma_{i,p} / \Gamma \| = \max_{\ell} \| \Gamma_{i,p} / \Gamma_{i,p} / \Gamma_{i,p} / \Gamma_{i,p} \| \).

Henceforth, fix the index \( \ell \) of one such subspace and let \( \Gamma := \Gamma_{i,\ell} \) denote the matrix projected onto \( \Pi_{\ell} \).

\[
\| \Gamma_{i,p} \Gamma_{i,p}^{-1} - v \| = \max_{v \in H_{\ell}} \left( \frac{\| \Gamma_{i,p} \Gamma_{i,p}^{-1} - v \|}{\| v \|} \right)
\]

\[
= \max_{w \in H_{\ell}} \left( \frac{\| \Gamma_{i,p} w \|}{\| w \|} \right)
\]

\[
= \frac{\| \Gamma_{i,p} w \|}{\| w \|}
\]

\[
\leq 1 + \frac{\| \Gamma_{i,p} - \Gamma \| w \|}{\| w \|}
\]

\[
\leq 1 + \frac{\| \Gamma_{i,p} - \Gamma \|}{\| w \|}
\]

\[
= \Gamma_{i,p} - \Gamma = (\Gamma_{i,p} - \Gamma) \circ D_i
\]

\[
= \Gamma_{i,p} = \Gamma \circ Y_{i,p}
\]

\[
= 1 + \frac{\| \Gamma_{i,p} - \Gamma \|}{\| w \|}
\]

\[
\leq 1 + \frac{\| \Gamma_{i,p} - \Gamma \|}{\| w \|}
\]

\[
= 1 + 2 \frac{\| \Gamma \circ D_i \|}{\lambda_{\min}(\Gamma)}
\]

which proves the second part of the lemma, because \( \Gamma \) here denotes \( \Gamma_{i,\ell} \).

**Proof of Theorem 3(3)** Let \( \Pi_{\text{good}} = I - \Pi_{\text{bad}} \) denote the projector onto the orthogonal complement of the bad subspace, coined the good subspace. We upper-bound the success probability in the good subspace by \( \eta \) and in the bad subspace by \( \eta \). Let \( |\rho\rangle \) be a purification of the final density matrix \( \rho^{T} \), \( |\rho_{\text{bad}}\rangle = \frac{\Pi_{\text{bad}}|\rho\rangle}{\|\Pi_{\text{bad}}|\rho\rangle\|} \), \( |\rho_{\text{good}}\rangle = \frac{\Pi_{\text{good}}|\rho\rangle}{\|\Pi_{\text{good}}|\rho\rangle\|} \), and \( \beta = \langle \Pi_{\text{good}}, \rho^{T} \rangle = \| \Pi_{\text{good}} |\rho\rangle \|^2 \). Decompose

\[
|\rho\rangle = \sqrt{1 - \beta} |\rho_{\text{bad}}\rangle + \sqrt{\beta} |\rho_{\text{good}}\rangle.
\]

Since \( \| F_{z} |\rho_{\text{bad}}\rangle \|^2 = \| F_{z} \Pi_{\text{bad}} |\rho_{\text{bad}}\rangle \|^2 \leq \| F_{z} \Pi_{\text{bad}} \|^2 \leq \eta \) for every output letter \( z \), the success probability of the algorithm would be at most \( \eta \) regardless of what the algorithm outputs, had the input register been in the state \( |\rho_{\text{bad}}\rangle \). The real output state is \( |\rho\rangle \). Since the trace distance of these two states is

\[
\| |\rho\rangle - |\rho_{\text{bad}}\rangle \| \leq \sqrt{1 - \beta} + \beta \leq 2 \sqrt{\beta},
\]

by [BVV97], the success probability on \( |\rho\rangle \) is at most \( \eta + 4 \sqrt{\beta} \). On the other hand, we assumed that the algorithm has success probability at least \( \eta + 4 \zeta \), hence \( \beta \geq \zeta^2 \). The progress function at the end takes value

\[
W^{T} = \lambda \cdot \Pi_{\text{good}}, \rho^{T} = \beta \lambda \geq \zeta^{4} \lambda,
\]

which is what we had to prove.
4 Applications

In this section, we reprove all known bounds obtained by the subspace-analysis technique of Ambainis. We only consider Boolean functions. The input oracle rotates the phase by a factor of \((-1)^{px_i}\), and the only nontrivial case is \(p = 1\). We thus omit \(p\) and write just \(Z_i, \Gamma_i\) instead of \(Z_{i,1}, \Gamma_{i,1}\).

4.1 Search

Let \(X = \{x \in \{0,1\}^n : |x| = 1\}\) and \(f(x) = i\) such that \(x_i = 1\). In other words, there is exactly one 1 in an \(n\)-bit string and we have to find it. One can quickly estimate the multiplicative adversary bound as follows.

**Lemma 7** \(\text{MADV}_{n-1,4\zeta}(f) = \Omega(\zeta^2 \sqrt{n})\).

**Proof** Let \(q > 1\) be a constant whose value we fix later. Define the following unit vectors: \(v = \frac{1}{\sqrt{n}}(1, \ldots, 1)\) and \(v_i = \frac{1}{\sqrt{n(n-1)}}(1, \ldots, 1 - n, 1 - n, \ldots, 1)\) with \(1 - n\) on the \(i\)-th position. Note that \(v \perp v_i\), but \(v_i \not\perp v_j\) for \(i \neq j\). Define the following adversary matrix:

\[
\Gamma = (1-q)|v\rangle \langle v| + qI,
\]

where \(I\) is the identity matrix. \(\Gamma\) has two eigenspaces: \(\Gamma v = v\), and \(\Gamma v_i = q v_i\). The success probability in the subspace of \(v\) is \(\eta = 1/n\). Let \(\lambda = ||\Gamma|| = q\).

We apply Corollary 6 with trivial block-diagonalization \(\Pi = \{I\}\). Then \(\lambda_{\min}(\Gamma) = 1\). \(\Gamma \circ D_i\) consists of an \(1 \times (n-1)\) block \(\frac{1}{n^2}(1, \ldots, 1)\) and its adjoint, hence \(||\Gamma \circ D_i|| = \sqrt{n-1} \cdot (q-1)/n < (q-1)/\sqrt{n}.\) Hence

\[
\text{MADV}_{n-1,4\zeta}(f) \geq \frac{\log(\frac{\zeta^2 q}{2(q-1)})}{\sqrt{n}}.
\]

We set \(q = 2/\zeta^2\) to make the logarithm positive. \(\square\)

It turns out that the rough analysis in the previous lemma loses a quadratic factor in the success probability. Let us compute exactly the eigenvalues of \(\Gamma_i \Gamma_i^{-1}\). Thanks to the symmetry, it is sufficient to only consider one case \(i = 1\).

**Theorem 8** \(\text{MADV}_{n-1,4\zeta}(f) = \Omega(\zeta \sqrt{n})\).

**Proof** We use the same adversary matrix Eqn. (4). We could compute \(\Gamma_1 \Gamma_1^{-1}\) explicitly, but we instead choose to demonstrate the block-diagonalization process. Define a complete set of orthogonal projectors \(\Pi = \{\Pi_2, \Pi_{\text{triv}}\}\) with a 2-dimensional subspace \(\Pi_2 = |v\rangle \langle v| + |v_1\rangle \langle v_1|\) and its orthogonal complement \(\Pi_{\text{triv}} = I - \Pi_2\). Define \(|w_2\rangle = \Pi_{\text{triv}}|v_2\rangle = |v_2\rangle - \langle v_1|v_2\rangle |v_1\rangle = \frac{1}{\sqrt{(n-1)n}}(0,2-n,1,\ldots,1)\) for which \(v_1 \perp w_2\), and define similarly \(w_3, \ldots, w_n\). Then \(\Pi_{\text{triv}}\) is spanned by \(w_2, \ldots, w_n\). \(Z_1w_i = w_i\) implies \(\Pi_{\text{triv}}Z_1 = \Pi_{\text{triv}}\). Since \(Z_1\) is unitary, \(Z_1\) is block-diagonal in \(\Pi\). Now,

\[
\Pi_2 \Gamma = |v\rangle \langle v| + q |v_1\rangle \langle v_1|
\]

and \(\Pi_{\text{triv}} \Gamma = q(I - |v\rangle \langle v| - |v_1\rangle \langle v_1|)\) = \(q \Pi_{\text{triv}}\), and hence \(\Gamma\) is also block-diagonal in \(\Pi\). We now analyze the diagonal blocks of \(\Gamma_i \Gamma_i^{-1}\) in this “basis”. We already know that \(\Pi_{\text{triv}}Z_1 = \Pi_{\text{triv}}\) and hence \(\Gamma_1 \Gamma_1^{-1} = I\) on the trivial subspace. It remains to examine the non-trivial subspace \(\Pi_2\).

In the orthonormal basis \(\{|v\rangle, |v_1\rangle\}\),

\[
\Gamma = \begin{pmatrix}
1 & 0 \\
0 & q
\end{pmatrix}, \quad Z_1 = \frac{1}{n} \begin{pmatrix}
n-2 & 2\sqrt{n-1} \\
2\sqrt{n-1} & 2 - n
\end{pmatrix},
\]
and the eigenvalues of $\Gamma_1 \Gamma^{-1} = Z_1 \Gamma Z_1 \Gamma^{-1}$ are $1 \pm \frac{2(q-1)}{\sqrt{q}} + O(\frac{1}{\sqrt{n}})$. Hence $\|\Gamma_1/\Gamma\| \approx 1 + \frac{2(q-1)}{\sqrt{q}}$, and by Corollary 4, the multiplicative adversary bound is

$$MADV_{n^{-1/4}}(f) \geq \frac{\log(\zeta^2 \lambda)}{\log(1 + 2(q-1)/\sqrt{q}n)} \geq \frac{\log(\zeta^2 q) \sqrt{q}}{2(q-1)} \sqrt{n},$$

where we have used that $\log(1 + x) \leq x$. This is by a factor of $\sqrt{q}$ larger than the bound given by Eqn. (5). Again, we set $q = 2/\zeta^2$ and finish the proof. \hfill \Box

The multiplicative adversary bound is stronger than the additive adversary bound for success probabilities polynomially small. By Corollary 2, the additive adversary bound for the decision version of this problem is

$$\text{ADV}_{\zeta^{-1}}(f) = 1 - \frac{\sqrt{1 - 2\zeta(1 + 2\zeta)}}{2} \sqrt{n} = 1 - \frac{\sqrt{1 - 4\zeta^2}}{2} \sqrt{n} \approx 1 - \frac{1 - 2\zeta^2}{2} \sqrt{n} = \zeta^2 \sqrt{n}.$$

### 4.2 \textit{t}-fold search

This is a generalization of the search problem, where we have to find $t$ ones. Let $X = \{x \in \{0,1\}^n : |x| = t\}$ and $f(x) = J$ such that $J \subseteq [n]$, $|J| = t$, and $x_J = 1$. The additive adversary implies that the bounded-error quantum query complexity of $f$ is $\Omega(\sqrt{1/n})$. The multiplicative adversary gives the same bound even for an exponentially small success probability! This whole section is based on the analysis by Ambainis [Amb05] translated to our framework.

**Theorem 9 ([Amb05])** \textit{The exists a constant $c < 1$ such that $MADV_{c, c'}(f) = \Omega(\sqrt{n})$}.

**Proof** Fix a $1 < q < O(1)$ and set $\lambda = q^{l/2}$. Define the following adversary matrix:

$$\Gamma = \sum_{j=0}^{t} q^j \Pi_{S_j},$$

where $\Pi_S$ denotes the projector onto the subspace $S$, $S_j = T_j \cap T_{j-1}^\perp$, and $T_j$ is the space spanned by $|\psi_j\rangle = \frac{1}{\sqrt{\binom{n}{t-j}}} \sum_{x:|x| = t \atop x_j = 1} |x\rangle$ for $J \subseteq [n]$ with $|J| = j$.

Denote $|\tilde{\psi}_j\rangle = \Pi_{T_{j-1}^\perp} |\psi_j\rangle$. These projected states are neither normalized nor orthogonal for $j > 0$. Denote $|\hat{\psi}_j\rangle = |\tilde{\psi}_j\rangle / \|\tilde{\psi}_j\|$. Note that $S_j$ is spanned by $|\hat{\psi}_j\rangle$.

**Block-diagonalization of $\Gamma$ and $Z_{i,p}$** Thanks to the symmetry, it is sufficient to only consider the case $i = 1$ of querying the first input bit. As we say above, the only nontrivial case is $p = 1$. We present a complete set of orthogonal projectors $\Pi$ in which both $\Gamma$ and $Z_1$ are block-diagonal. Let

$$|\psi_J^b\rangle = \frac{1}{\sqrt{\binom{n-j-1}{t-j-b}}} \sum_{x:|x| = t \atop x_j = b \atop x_{j-1} = 1} |x\rangle$$

for $J \subseteq [n]$ such that $1 \not\in J$.

$$|\psi_J^b\rangle = \Pi_{T_{j-1}^\perp} |\psi_J^b\rangle$$

with $T_{j,b}$ spanned by $|\psi_J^b\rangle$ with $|J| = j$.

$$|\psi_J^b\rangle = |\tilde{\psi}_J^b\rangle / \|\tilde{\psi}_J^b\|$$

Let $S_{j,b} = T_{j,b} \cap T_{j-1}^\perp$. Then the following holds:
• Let $|\tilde{\psi}_{j}^{a,b}\rangle$ denote the vector $a|\tilde{\psi}_{j}^{a}\rangle + b|\tilde{\psi}_{j}^{b}\rangle$. Let

$$
\begin{align*}
\alpha_j' = \sqrt{\frac{n-t}{n-j}} \|\tilde{\psi}_{j}^{a}\| & \quad \beta_j' = \sqrt{\frac{t-j}{n-j}} \|\tilde{\psi}_{j}^{b}\|
\alpha_j = \frac{\alpha_j'}{\sqrt{(\alpha_j')^2 + (\beta_j')^2}} & \quad \beta_j = \frac{\beta_j'}{\sqrt{(\alpha_j')^2 + (\beta_j')^2}}
\end{align*}
$$

We also denote them $\alpha, \beta$ if the index $j$ is clear from the context. Note that $\alpha^2 + \beta^2 = 1$. Then $|\tilde{\psi}_{j}^{a}\rangle \in S_j$ and $|\tilde{\psi}_{j}^{\beta,-\alpha}\rangle \in S_{j+1}$ [ASW06, Claim 15]. These two new vectors span the same subspace as $|\tilde{\psi}_{j}^{a}\rangle$ and $|\tilde{\psi}_{j}^{b}\rangle$.

• [ASW06, Claim 16] $S_{j,0}$ and $S_{j,1}$ have the same dimension and the mapping

$$
M'|0x_2 \ldots x_n\rangle \rightarrow \sum_{\ell, x_\ell = 1} |1x_2 \ldots x_{\ell-1}0x_{\ell+1} \ldots x_n\rangle
$$

is a multiple $M' = c_j M_j$ of some unitary operation on $S_{j,0} \rightarrow S_{j,1}$ that maps $M_j |\tilde{\psi}_{j}^{a}\rangle \rightarrow |\tilde{\psi}_{j}^{b}\rangle$.

• Pick any orthonormal basis $\{|\varphi_{j,\ell}\rangle\}_\ell$ for each $S_{j,\ell}$ (the defining basis $|\tilde{\psi}_{j}^{a}\rangle$ is not orthogonal). For $j < \ell$, define projectors $\Pi_{j,\ell} = |\varphi_{j,\ell}\rangle \langle \varphi_{j,\ell}| + M_{j} |\varphi_{j,\ell}\rangle \langle M_{j}^{\ast}$. Note that if some $|\varphi_{j,\ell}\rangle = |\tilde{\psi}_{j}^{a}\rangle$, then

$$
\Pi_{j,\ell} = |\tilde{\psi}_{j}^{a}\rangle \langle \tilde{\psi}_{j}^{a}| + |\tilde{\psi}_{j}^{b}\rangle \langle \tilde{\psi}_{j}^{b}| = |\tilde{\psi}_{j}^{\alpha,\beta}\rangle \langle \tilde{\psi}_{j}^{\alpha,\beta}| + |\tilde{\psi}_{j}^{\beta,-\alpha}\rangle \langle \tilde{\psi}_{j}^{\beta,-\alpha}|
$$

due to the basis change mentioned in the first item above. Thus $\Pi_{j} = \{|\varphi_{j,\ell}\rangle\}_\ell$ is a complete set of orthogonal projectors for $S_{j,0} \oplus S_{j,1}$, or, equivalently, for the subspace of $S_j \cup S_{j+1}$ spanned by $|\tilde{\psi}_{j}\rangle$ and $|\tilde{\psi}_{j,\ell}(11)\rangle$ with $|J| = j$ and $1 \notin J$. It follows that

$$
\Pi = \bigcup \{|\varphi_{j,\ell}\rangle\}_\ell \quad \bigcup \{|\varphi_{j,\ell}\rangle\}_\ell
$$

is a complete set of orthogonal projectors for the whole input space $T_i$.

Let us verify that $\Pi$ indeed block-diagonalizes $\Gamma$ and $Z_1$. To compute the images of the basis states of each projector $\Pi_{j,\ell}$, we use a double decomposition like in Eqn. (7). First, since $|\varphi_{j,\ell}\rangle \in S_{j,0}$ and $M_j |\varphi_{j,\ell}\rangle \in S_{j,1}$, $Z_1 |\varphi_{j,\ell}\rangle = |\varphi_{j,\ell}\rangle$ and $Z_1 M_j |\varphi_{j,\ell}\rangle = -M_j |\varphi_{j,\ell}\rangle$, hence $Z_1$ is block-diagonal in $\Pi$. Second, if we denote $|\varphi_{j,\ell}(a,b)\rangle = a |\varphi_{j,\ell}\rangle + b M_j |\varphi_{j,\ell}\rangle$, then $|\varphi_{j,\ell}(a,\beta)\rangle \in S_{j}$ and $|\varphi_{j,\ell}(\beta,-\alpha)\rangle \in S_{j+1}$, because both $|\varphi_{j,\ell}\rangle$ and $M_j |\varphi_{j,\ell}\rangle$ are just linear combinations with the same coefficients of states $|\tilde{\psi}_{j}^{a}\rangle$ and $|\tilde{\psi}_{j}^{b}\rangle$ respectively. We conclude that

$$
\Gamma |\varphi_{j,\ell}(a,b)\rangle = q^{\ell} |\varphi_{j,\ell}(a,\beta)\rangle \quad \text{and} \quad \Gamma |\varphi_{j,\ell}(\beta,-\alpha)\rangle = q^{j+1} |\varphi_{j,\ell}(\beta,-\alpha)\rangle,
$$

hence $\Gamma$ is also block-diagonal in $\Pi$.

**Eigenvalues of $\Gamma_1/\Gamma$ on $\Pi_{j,\ell}$**

Consider the orthonormal basis $B_1 = \{|\varphi_{j,\ell}(a,b), M_j |\varphi_{j,\ell}\rangle\}$ of $\Pi_{j,\ell}$. Let $B = (a - \beta \cdot \beta) \otimes B$ denote the self-adjoint unitary operator changing the basis from $B_1$ to $\{|\varphi_{j,\ell}(a,\beta), |\varphi_{j,\ell}(\beta,-\alpha)\rangle\}$. Then, in the basis $B_1$,

$$
\begin{align*}
\Gamma_1 \Gamma^{-1} \Pi_{j,\ell} = & \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} B^* \begin{pmatrix} q^j & q^{j+1} \\ 0 & q^{-j-1} \end{pmatrix} B \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} B^* \begin{pmatrix} q^{-j} & 0 \\ 0 & q^{j+1} \end{pmatrix} B
\end{align*}
$$

$$
= \begin{pmatrix} (1 + 2\alpha^2 \beta^2 (q - 1)^2/q) I + 2\alpha \beta q - 1/q \begin{pmatrix} \beta^2 + \alpha^2 q & \beta^2 q \\ \beta^2 q & \alpha^2 q \end{pmatrix} \end{pmatrix}.
$$

A straightforward calculation shows that $\Gamma_1 \Gamma^{-1} \Pi_{j,\ell}$ has eigenvalues

$$
1 + 2\alpha^2 \beta^2 (q - 1)^2/q \pm 2\alpha \beta q - 1/q \sqrt{(\alpha^2 + \beta^2 q)(\beta^2 + \alpha^2 q)}.
$$
We use a trivial upper bound $\alpha \leq 1$, and an upper bound $\beta \leq \sqrt{2t/n}$ [AŠW06, Claim 19], which easily follows from the (non-trivial) computation of $\|\tilde{\psi}_j\| = \sqrt{\frac{(n-t+\lambda_{j})}{(n-\lambda_{j})}}$ [AŠW06, Claim 18]. By using $1 < q \leq nt$, and $q = O(1)$, we obtain

$$
\|\Gamma_1^{t-1} \Pi_{j,\ell}\| \leq 1 + \frac{4t(q-1)^2}{nq} + 2 \sqrt{\frac{2tq-1}{q}} \sqrt{3(q+2t/n)} < 1 + 6\sqrt{\frac{2t}{nq}(q-1) + O(\frac{1}{q})}.
$$

**Eigenvalues of $\Gamma_1 / \Gamma$ on the trivial subspace** Let us revisit the trivial subspace $S_{t,0}$ and make sure that the block-diagonalization is right there, too. We claim that $S_{t,0} \subseteq S_t$. Since $|\psi_0\rangle = |\psi_J\rangle$ for $|J| = t$ and $1 \notin J$, we get $T_{t,0} \subseteq T_t$, and thus it suffices to prove $S_t = T_{t,0} \cap T_{t,0}^\perp \subseteq T_{t-1,1}^\perp$. It holds that $T_{t,0} \subseteq T_{t-1,1}$ due to a different value of the first input bit. Also, we know that $T_{t} \subseteq T_{t,0} \oplus T_{t,1}$, hence $T_{t,0}^\perp \cap T_{t,1}^\perp \subseteq T_{t}^\perp$ and the proof is finished.

Let $|w\rangle \in S_{t,0}$. $|w\rangle$ is an eigenvector of $\Gamma$, because it lies in $S_t$. Since $Z_1 |w\rangle = |w\rangle$, we conclude that $\Gamma_1^{-1} |w\rangle = |w\rangle$ and $S_{t,0}$ is indeed a trivial subspace.

**Upper-bounding $\eta$** Since $\lambda = q^{t/2}$, we have to upper-bound $\|F_x|\varphi\| \leq \eta$ for all $|\varphi\rangle \in T_{t/2}$. Since the dimension of $T_{t/2}$ is $\binom{n}{t/2}$ and the number of possible outcomes is $\binom{n}{t}$, using [Nay99], the success probability is at most $\eta \leq \left(\binom{n}{t/2}/\binom{n}{t}\right)$, which is exponentially small in $t$.

**Multiplicative adversary bound** Since $\lambda = q^{t/2}$ and $\|\Gamma_1 / \Gamma\| = \max_j \|\Gamma_1^{t-1} \Pi_{j,\ell}\|$, by Corollary 4, the multiplicative adversary bound is

$$
\text{MADV}_{\eta, \zeta}(f) \geq \frac{\log(\zeta^2 q^{t/2})}{\log(1 + 6(q-1)/\sqrt{2t/n})} \geq \frac{\varepsilon \log q + 2 \log \zeta}{6(q-1)^2/\sqrt{2t/q}} \sqrt{n} = \frac{\log q - 4 \log(\zeta^{-1/2})}{12(q-1)^2/\sqrt{2/q}} \sqrt{n},
$$

which is $\geq \frac{\log^2 2}{2t} \sqrt{n}$ for $q = 2$ and $\zeta \geq 2^{-t/8}$.

### 4.3 $t$-threshold function

The decision version of the $t$-fold search problem is the $t$-threshold function $X = \{ x \in \{0,1\}^n : |x| \in \{t-1, t\}\}$ and $f(x) = |x| - t + 1$. Here one can always achieve success probability 1/2 by random guess, hence we want to upper-bound the bias from 1/2. The analysis in this section is based on Ambainis’s method [ASW06] translated to our framework.

**Theorem 10** ([AŠW06]) $\text{MADV}_{1/2, \zeta}(f) = \Omega(\zeta^2 \sqrt{n})$.

We conjecture that the true bound is $O(\zeta \sqrt{n})$, however we are unable to analyze the $4 \times 4$ matrix in the proof exactly and we have to use the simpler bound from Corollary 6 that seemingly loses exactly the same quadratic factor as in Lemma 7.

**Proof (sketch)** We conduct the proof similarly to Theorem 9, but now we use eigenspaces spanned by uniform superpositions of both $(t-1)$-weight and $t$-weight strings. Define the following adversary matrix with $q = 1 + 4 \log(2/\zeta)$ and $\lambda = q^{t/2}$:

$$
\Gamma = \sum_{j=0}^{t/2-1} q^j \Pi_{S_{j,+}} + q^{t/2} \left( \sum_{j=t/2}^{t-1} \Pi_{S_{j,+}} + \sum_{j=0}^{t} \Pi_{S_{j,-}} \right).
$$

10
where $S_{j,\pm}$ is spanned by $|\tilde{\psi}_{J,\pm}\rangle = \frac{1}{\sqrt{2}}(|\psi_{J,0}\rangle \pm |\psi_{J,1}\rangle)$,

$$|\psi_{J,a}\rangle = \frac{1}{\sqrt{(t+\eta-a-j)}} \sum_{x_1,\ldots,x_j = -1}^{+1} |x\rangle,$$

and the tilde and double-dot states are defined as usual.

Let us explain the intuition behind this construction. We have to put all minus subspaces inside the good subspace of $\Gamma$, otherwise some $|v\rangle = |\psi_{J,a}\rangle = \frac{1}{\sqrt{2}}(|\psi_{J,+}\rangle + |\psi_{J,-}\rangle)$, for which $\|F_0|v\rangle\| = 1$, lies in $S_{j,+} \oplus S_{j,-} \subseteq T_{bad}$, and the success probability in the bad subspaces could only be upper-bounded by the trivial $\eta = 1$. This way, all states from bad subspaces lie inside $T_{i/2,+}$ and $\eta = 1/2$. On the other hand, we mark the plus subspaces above $j \geq t/2$ as good instead of bad, because it allows us to prove a stronger bound on the denominator. We do not lose much in the numerator.

**Block-diagonalization of $\Gamma$ and $Z_1$**  Like in the proof of Theorem 9, we naturally decompose the basis states $|\tilde{\psi}_{J,a}\rangle$ with $1 \notin J$ onto $|\tilde{\psi}_{J,a,b}\rangle$ by fixing the first input bit to $b$. For the same reasons, some linear combinations of these states lie in $S_{j,\pm}$ and $S_{j+1,\pm}$. In particular, if for a $v = (\psi_{00}, \psi_{01}, \psi_{10}, \psi_{11})$ we let $|\tilde{\psi}_{j}^v\rangle$ denote $\psi_{00}|\tilde{\psi}_{J,0,0}\rangle + \psi_{01}|\tilde{\psi}_{J,0,1}\rangle + \psi_{10}|\tilde{\psi}_{J,1,0}\rangle + \psi_{11}|\tilde{\psi}_{J,1,1}\rangle$, then $\Gamma|\tilde{\psi}_{j}^v\rangle = |\tilde{\psi}_{j}\rangle$ with $w = BG_{j}B^*v$ [ASW06, Claim 17], where

$$B = \frac{1}{\sqrt{2}} \begin{pmatrix}
\alpha_0 & \beta_0 & \alpha_0 & \beta_0 \\
\beta_0 & -\alpha_0 & -\beta_0 & \alpha_0 \\
\alpha_1 & \beta_1 & -\alpha_1 & -\beta_1 \\
-\alpha_1 & \beta_1 & -\alpha_1 & -\beta_1
\end{pmatrix}, \quad G_j = \begin{pmatrix}
q^j & 0 & 0 & 0 \\
0 & q^{j+1} & 0 & 0 \\
0 & 0 & q^j & 0 \\
0 & 0 & 0 & q^j
\end{pmatrix}, \quad Y = \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & -1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & -1
\end{pmatrix},$$

and $\alpha_a, \beta_a$ for an $a \in \{0, 1\}$ (and an implicit index $j$) are defined by equation Eqn. (6) with the threshold value $t := t - 1 + a$. In other words, the columns of $B$ are vectors $v$ that put $|\tilde{\psi}_{j}^v\rangle$ inside $S_{j,+,S_{j,+,S_{j,-},S_{j,-},S_{j+1,-}}$, respectively. Furthermore, the subspaces $S_{j,a,b}$ for $a, b \in \{0, 1\}$, spanned by $|\tilde{\psi}_{J,a,b}\rangle$, have the same dimension and there are 3 unitaries that map $|\tilde{\psi}_{J,0,0}\rangle \to |\tilde{\psi}_{J,a,b}\rangle$, hence one can form a complete set of orthogonal projectors $\Pi = \{\Pi_{j,\ell}\}_{j,\ell} \cup \Pi_{triv}$ that block-diagonalizes $\Gamma$. Each projector $\Pi_{j,\ell}$ is 4-dimensional. $Z_1$ is trivially block-diagonal in $\Pi$, because $Z_1|\tilde{\psi}_{J,a,b}\rangle = (-1)^{\delta b} |\tilde{\psi}_{J,a,b}\rangle$, or, equivalently, $Z_1|\tilde{\psi}_{j}^w\rangle = |\tilde{\psi}_{j}^w\rangle$ with $w = Yv$.

**Spectral norm of $\Gamma_1/\Gamma$ on $\Pi_{j,\ell}$**  Recall $\Gamma_1 = Z_1^* \Gamma Z_1$ and denote $\Gamma_j^v = \Gamma_{j,\ell} = BG_{j}B^*$ for some $\ell$. Then

$$\Gamma_1/\Gamma_j^v = \Gamma_1 \Gamma^{-1}_j \Pi_{j,\ell} = Y BG_{j}B^*Y \cdot BG_{j}^{-1} B^*.$$

This matrix is too hard to analyze directly, hence we apply Corollary 6 rather than Corollary 4. Compute

$$\frac{2\|\Gamma_j^v \circ D_1\|}{\alpha_{\min}(\Gamma_j^v)} = \frac{2}{q^j}(BG_{j}B^*) \circ D_1||, \quad \text{where} \quad D_1 = \begin{pmatrix}
0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0
\end{pmatrix}.$$

Write the matrix $(BG_{j}B^*) \circ D_1$ after swapping the second and third row and column as $-\frac{q^j}{4}\left(H_j^* d^0_{H_j} \right)$ with

$$H_j = \begin{pmatrix}
\alpha_0 \beta_0 (q-1) & \alpha_1 \beta_0 (q^{j/2-j-1}) & -\alpha_1 \beta_0 (q^{j/2-j-1}) & \alpha_0 \beta_0 (q^{j/2-j-1}) \\
\alpha_1 \beta_0 (q^{j/2-j-1}) & -\alpha_1 \beta_0 (q^{j/2-j-1}) & \alpha_1 \beta_0 (q^{j/2-j-1}) & -\alpha_1 \beta_0 (q^{j/2-j-1}) \\
-\alpha_0 \beta_0 (q^{j/2-j-1}) & -\alpha_0 \beta_0 (q^{j/2-j-1}) & \alpha_0 \beta_0 (q^{j/2-j-1}) & -\alpha_0 \beta_0 (q^{j/2-j-1}) \\
\alpha_0 \beta_0 (q^{j/2-j-1}) & -\alpha_0 \beta_0 (q^{j/2-j-1}) & -\alpha_0 \beta_0 (q^{j/2-j-1}) & \alpha_0 \beta_0 (q^{j/2-j-1})
\end{pmatrix},$$

$$\|H_j\| \leq (q-1) \left\| \begin{pmatrix}
\alpha_0 \\
\alpha_1 \\
\beta_0 \\
\beta_1
\end{pmatrix} \cdot \begin{pmatrix}
\alpha_0 \\
\alpha_1 \\
\beta_0 \\
\beta_1
\end{pmatrix} \right\| + (q^{j/2-j-1})(\alpha_1 \beta_0 - \alpha_0 \beta_1) \begin{pmatrix}
0 & 1 \\
-1 & 0
\end{pmatrix} \begin{pmatrix}
0 & 1 \\
-1 & 0
\end{pmatrix}$$
Use $\alpha_a \leq 1$, and $\beta_a \leq \sqrt{2t/n}$ and $|\alpha_1\beta_0 - \alpha_0\beta_1| = O(1/\sqrt{tn})$ for $j \leq t/2$ [ÅSW06, Claim 19 and 20]. Then substitute $q = 1 + \frac{4\log(2/\zeta)}{\zeta}$ and bound $\lambda = q^{t/2} \approx \varepsilon^2 \log(2/\zeta) = 4/\zeta^2$.

$$\|H_j\| \leq 2(q-1)\sqrt{\frac{2t}{n}} + (q^{t/2} - 1)O\left(\frac{1}{\sqrt{tn}}\right) = O(1) \cdot \log(2/\zeta) + 4/\zeta^2 = O\left(\frac{1}{\zeta^2 \sqrt{tn}}\right).$$

We conclude that

$$\min_j \frac{\lambda_{\min}(\Gamma_j)}{2\|\Gamma \circ D_1\|} = \Omega(\zeta^2 \sqrt{tn}).$$

As we say above, this bound is only valid for $j \leq t/2$. However, if $j \geq t/2$, then $G_j = q^{t/2}I$, $\Gamma_1/\Gamma_j = I$, and the analysis in this subspace is trivial. This is exactly the reason why we mark the subspaces $S_{j,+}$ for $j \geq t/2$ as good.

**Analysis of the trivial subspaces** For $j \in \{t-1, t\}$, the projectors $\Pi_{j,\ell}$ have smaller dimension than $4 \times 4$, because there are not enough basis states. In particular, for $|J| = t - 1$, there are only 3 types of basis states $|\psi_{J,0,0}\rangle \in S_{t-1,0,0} \subset S_{t-1,0}$, and $|\psi_{J,1,0}\rangle$ and $|\psi_{J,1,1}\rangle$ with $\alpha|\psi_{J,0,0}\rangle + \beta|\psi_{J,1,1}\rangle \in S_{t-1,1}$ and $\beta|\psi_{J,1,0}\rangle - \alpha|\psi_{J,1,1}\rangle \in S_{t,1}$. Hence their linear combinations fall into the following subspaces: $(1, \alpha, \beta) \in S_{t-1,+,}, (1, -\alpha, -\beta) \in S_{t-1,},$, and $(0, \beta, -\alpha) \in S_{t,1} = S_{t,-}$. Note that $S_{t,-}$ has a different definition than other $S_{j,-}$, and that there is no subspace $S_{t,+}$. For, $|J| = t$, the situation is simpler, because there are only basis states $|\psi_{J,1,0}\rangle \in S_{t,0,0} \subset S_{t,1}$ and $S_{t,-}$. We conclude that even the projectors onto the trivial subspaces block-diagonalize $\Gamma$ and $Z_1$.

Now, the actual analysis of the norm of $\Gamma_1/\Gamma$ on these trivial subspaces is not needed, because $\Gamma = q^{t/2}I$ on $\Pi_{t-1,\ell}$ or $\Pi_{t,\ell}$. We conclude that the norm there is exactly 1.

**Multiplicative adversary bound** By Corollary 6, using the symmetry over all $i$ and $\zeta^2 \lambda = \zeta^2 q^{t/2} \approx 4$,

$$\text{MADV}_{1/2,4\zeta}(f) \geq \log(\zeta^2 \lambda) \cdot \min_j \frac{\lambda_{\min}(\Gamma_j)}{2\|\Gamma \circ D_1\|} = \Omega(\zeta^2 \sqrt{tn}).$$

\[\square\]

### 4.4 Designing $\Gamma$ for a general function

After having presented optimal multiplicative adversary matrices for several problems, let us make a note on how to design a good $\Gamma$ in general. It seems that we don’t have too much freedom. All known good multiplicative adversary matrices $\Gamma$ have the following structure: $\Gamma$ is a linear combination of projectors $S_j$, where $S_j$ is spanned by superpositions of input states consistent with fixing exactly $j$ input variables. This matrix is then simultaneously block-diagonalized with the query operator. The diagonal blocks typically overlap with some adjacent subspaces $S_j$ and $S_{j+1}$. To get a good estimate of the spectral norm of such a block, the minimal and maximal eigenvalue in this block must not differ too much. On the other hand, we want the spectral norm of $\Gamma$ be as large as possible, hence an optimal choice of the multiplicative coefficients seems to be $q^j S_j$ for some constant $q$, or more generally $(\Pi_{j,1} q_I) S_j$, with $q_I$ different in each subspace $S_i$ if the subspaces for different $i$ have significantly different properties.

The real difficulty seems to lie not in designing good subspaces $S_j$, but in their combinatorial analysis.
5 Direct product theorems

In this section we investigate the complexity of evaluating a function $f$ on $k$ independent instances simultaneously. We prove that the multiplicative adversary bound satisfies a strong direct product theorem (DPT). Roughly speaking it says that if we are asked to compute $f$ on $k$ independent inputs in time less than $k$ times the time for one instance, then the success probability goes exponentially down. Ambainis [ASW06] proved a DPT for $t$-threshold using these techniques. Here we show that his proof actually gives a DPT for any function that has a multiplicative adversary lower bound.

For a function $f : X \to \Sigma_0^k$ with $X \subseteq \Sigma_k^*$ and $k \geq 1$, let $f^{(k)} : X^k \to \Sigma_0^k$ such that $f(x_1, \ldots, x_k) = (f(x_1), \ldots, f(x_k))$. An algorithm succeeds with computing $f^{(k)}$ if all individual instances are computed right.

**Theorem 11** For every function $f$ with $\eta \leq \frac{1}{2}$, and $k \geq 361$, $\text{MADV}_{\eta^{2k/5}, \zeta^{k/10}}(f^{(k)}) \geq \frac{k}{10} \cdot \text{MADV}_{\eta, \zeta}(f)$.

**Proof** Let $\Gamma, \lambda$ denote the optimal multiplicative adversary matrix for $f$ with success $\eta$, and its threshold value for good subspaces. We construct $\Gamma', \lambda'$ for $f^{(k)}$ as follows [ASW06, Appendix A.1]:

$$\Gamma' = \Gamma^{\otimes k}, \quad \lambda' = \lambda^{k/10}.\$$

We prove that $\max_{i'p} \|\Gamma'_{i',p}/\Gamma'\| = \max_{i,p} \|\Gamma_{i,p}/\Gamma\|$. This is because, for an $i' = jn + i$, $\Gamma'_{i',p} = Z_{i',p}^{\otimes j} Z_{i,p}^{\otimes (k-1-j)}$, and thus $\Gamma^{n,i,p}/\Gamma = I^{\otimes j}(\Gamma_{i,p}/\Gamma) \otimes I^{\otimes (k-1-j)}$. Therefore, by Corollary 4, if we choose $\zeta' = \zeta^{k/10}$, the multiplicative adversary bound is

$$\text{MADV}_{\eta, \zeta'}(f^{(k)}) \geq \frac{\log(\zeta'^2 \lambda')}{\log(\max_{i,p} \|\Gamma_{i,p}/\Gamma\|)} = \frac{k}{10} \cdot \frac{\log(\zeta^2 \lambda)}{\log(\max_{i,p} \|\Gamma_{i,p}/\Gamma\|)} = \frac{k}{10} \cdot \text{MADV}_{\eta, \zeta}(f).$$

It remains to analyze the success $\eta'$ of the composed function $f^{(k)}$.

**Upper-bounding $\eta'$** Let $T_{\text{bad}}, T_{\text{good}}$ denote the bad and good subspace of $\Gamma$. For a $v \in \{\text{bad, good}\}^k$, let $|\varphi\rangle \in T_{v_1} \otimes \cdots \otimes T_{v_k}$ be a product quantum state such that $\|\Gamma'_{v}\| < \lambda'$. Since all eigenvalues of $\Gamma$ are at least 1, if a subspace of $\Gamma'$ corresponds to an eigenvalue less than $\lambda'$, only less than $k/10$ individual subspaces out of $k$ can be the good ones. This means that more than $9k/10$ instances lie in the bad eigenspace of $\Gamma$ and have thus success probability at most $\eta$. Since $|\varphi\rangle$ is a product state, the total success probability of computing all instances right is at most $\eta^{9k/10}$. We, however, have to upper-bound the success probability for all superposition states than can come from different combinations of $T_{v_i}$’s. In general,

$$|\varphi\rangle = \sum_{v \in \{\text{bad, good}\}^k, |v| < k/10} \alpha_v |\varphi_v\rangle, \quad \text{where } |\varphi_v\rangle \in T_{v_1} \otimes \cdots \otimes T_{v_k} \text{ and } |v| \text{ denotes #good subspaces.}$$

Our assumption about $f$ is that $\|F_z|v\rangle\|^2 \leq \eta$ for every $z$ and $|v\rangle \in T_{\text{bad}}$. Thus

$$\|((F_{z_1} \otimes \cdots \otimes F_{z_k})|\varphi\rangle)^2 = \left\| \sum_v \alpha_v \prod_i F_{z_i} |\varphi_v, i\rangle \right\|^2$$

$$\leq \left( \sum_v |\alpha_v|^2 \prod_i \|F_{z_i} |\varphi_v, i\rangle\| \right)^2$$

$$\leq \left( \sum_v |\alpha_v|^2 \right) \left( \sum_v \prod_i \|F_{z_i} |\varphi_v, i\rangle\| \right)^2$$

$$\leq \left( \sum_v |\alpha_v|^2 \right) \left( \sum_v \prod_i \|F_{z_i} |\varphi_v, i\rangle\| \right)^2 \sum_{v:|v| < k/10} 1$$

$$= \eta^{9k/10} \sum_{v:|v| < k/10} \left( \sum_{i=0}^{k/10} \left( \frac{k}{i} \right) \eta^{9k/10} \right)$$

$$= \eta^{9k/10} \sum_{i=0}^{k/10} \left( \frac{k}{i} \right) \eta^{9k/10}$$
Apply \((\binom{n}{k})^k\leq (\frac{ne}{e})^k\), \(\sqrt{10e} < 2\), \(k\sqrt{10e}^{k/2} < 2^{k/2}\) for \(k \geq 361\), and \(\eta \leq \frac{1}{2}\).

\[
\leq k(10e)^{k/10} \eta^{9k/10} \\
< 2^{k/2} \eta^{k/2} \eta^{2k/5} \leq \eta^{2k/5}.
\]

Note that in the case of the \(t\)-threshold function as the base function, the success probability is \(\eta = \frac{1}{2}\) in both bad (plus) and good (minus) subspaces, hence we could use a stronger bound \(2^{-k}\) instead of \(\eta^{9k/10}\). There is nothing special about the constant \(k \geq 361\); the DPT holds for all \(k\), but we have to take into account the multiplicative factor of \(k\) in the success \(\eta'\).

We conclude that \(\text{MADV}_{\eta^{2k/5},\zeta^{k/10}}(f) \geq \frac{k}{10} \cdot \text{MADV}_{\eta,\zeta}(f)\).

This technique also allows us to prove the direct product theorem when the \(k\) instances are distinct functions.
