\textbf{Abstract} — The global fit of the Standard Model to electroweak precision data, routinely performed by the LEP electroweak working group and others, demonstrated impressively the predictive power of electroweak unification and quantum loop corrections. We have revisited this fit in view of (i) the development of the new generic fitting package, \textit{Gfitter}, allowing flexible and efficient model testing in high-energy physics, (ii) the insertion of constraints from direct Higgs searches at LEP and the Tevatron, and (iii) a more thorough statistical interpretation of the results. \textit{Gfitter} is a modular fitting toolkit, which features predictive theoretical models as independent plugins, and a statistical analysis of the fit results using toy Monte Carlo techniques. The state-of-the-art electroweak Standard Model is fully implemented, as well as generic extensions to it. Theoretical uncertainties are explicitly included in the fit through scale parameters varying within given error ranges.

This paper introduces the \textit{Gfitter} project, and presents state-of-the-art results for the global electroweak fit in the Standard Model, and for a model with an extended Higgs sector (2HDM). Numerical and graphical results for fits with and without including the constraints from the direct Higgs searches at LEP and Tevatron are given. Perspectives for future colliders are analysed and discussed.

Including the direct Higgs searches, we find $M_H = 116.4^{+18.3}_{-1.3}$ GeV, and the 2σ and 3σ allowed regions $[114, 145]$ GeV and $[113, 168]$ and $[180, 225]$ GeV, respectively. For the strong coupling strength at fourth perturbative order we obtain $\alpha_S(M_Z^2) = 0.1193^{+0.0028}_{-0.0027}(\text{exp}) \pm 0.0001(\text{theo})$. Finally, for the mass of the top quark, excluding the direct measurements, we find $m_t = 178.2^{+9.8}_{-4.2}$ GeV. In the 2HDM we exclude a charged-Higgs mass below 240 GeV at 95% confidence level. This limit increases towards larger $\tan\beta$, e.g., $M_{H^\pm} < 780$ GeV is excluded for $\tan\beta = 70$.

1 Introduction

Precision measurements allow us to probe physics at much higher energy scales than the masses of the particles directly involved in experimental reactions by exploiting contributions from quantum loops. These tests do not only require accurate and well understood experimental data but also theoretical predictions with controlled uncertainties that match the experimental precision. Prominent examples are the LEP precision measurements, which were used in conjunction with the Standard Model (SM) to predict via multidimensional parameter fits the mass of the top quark \[m_t\], prior to its discovery at the Tevatron \[2, 3\]. Later, when combined with the measured top mass, the same approach led to the prediction of a light Higgs boson \[4\]. Other examples are fits to constrain parameters of Supersymmetric or extended Higgs models, using as inputs the anomalous magnetic moment of the muon, results on neutral-meson mixing, CP violation, rare loop-induced decays of \(B\) and \(K\) mesons, and the relic matter density of the universe determined from fits of cosmological models to data.

Several theoretical libraries within and beyond the SM have been developed in the past, which, tied to a multi-parameter minimisation program, allowed to constrain the unbound parameters of the SM \[5–8\]. However, most of these programs are relatively old, were implemented in outdated programming languages, and are difficult to maintain in line with the theoretical and experimental progress. It is unsatisfactory to rely on them during the forthcoming era of the Large Hadron Collider (LHC) and the preparations for future linear collider projects. Improved measurements of important input observables are expected and new observables from discoveries may augment the available constraints. None of the previous programs were modular enough to easily allow the theoretical predictions to be extended to models beyond the SM, and they are usually tied to a particular minimisation package.

These considerations led to the development of the generic fitting package \textit{Gfit} \[9\], designed to provide a framework for model testing in high-energy physics. \textit{Gfit} is implemented in C++ and relies on ROOT \[10\] functionality. Theoretical models are inserted as plugin packages, which may be hierarchically organised. Tools for the handling of the data, the fitting, and statistical analyses such as toy Monte Carlo sampling are provided by a core package, where theoretical errors, correlations, and inter-parameter dependencies are consistently dealt with. The use of dynamic parameter caching avoids the recalculation of unchanged results between fit steps, and thus significantly reduces the amount of computing time required for a fit.

The first theoretical framework implemented in \textit{Gfit} has been the SM predictions for the electroweak precision observables measured by the LEP, SLC and the Tevatron experiments. State-of-the-art calculations have been used, and – wherever possible – the results have been cross-checked against the \textit{ZFITTER} package \[5\]. For the \(W\) mass and the effective weak mixing angle, which exhibit the strongest constraints on the Higgs mass through radiative corrections, the full second order corrections are available \[11, 12\]. Furthermore, the corrections of order \(\mathcal{O}(\alpha^3)\) and the leading three-loop corrections in an expansion of the top-mass-squared \((m_t^2)\) are included. The partial and total widths of the \(Z\) are known to leading order, while for the second order only the leading \(m_t^2\) corrections are available \[13\]. Among the new developments included in the SM library is the fourth-order (3NLO) perturbative calculation of the massless QCD Adler function \[14\], contributing to the vector and axial-vector radiator functions in the prediction of the \(Z\) hadronic width (and other observables). It allows to fit the strong coupling constant with unique theoretical accuracy \[14, 15\].

Among the experimental precision data used are the \(Z\) mass, measured with relative precisions
of $2 \cdot 10^{-5}$, the hadronic pole cross section at the $Z$ mass and the leptonic decay width ratio of the $Z$ with $10^{-3}$ relative precision. The effective weak mixing angle $\sin^2 \theta_{\text{eff}}^\ell$ is known from the LEP experiments and SLD to a relative precision of $7 \cdot 10^{-4}$. The $W$ mass has been measured at LEP and the Tevatron to an overall relative precision of $3 \cdot 10^{-4}$. The mass of the top quark occurs quadratically in loop corrections of many observables. A precision measurement (currently $7 \cdot 10^{-3}$) is mandatory. Also required is the precise knowledge of the electromagnetic and weak coupling strengths at the appropriate scales. Energy-dependent photon vacuum polarisation contributions modify the QED fine structure constant, which at the $Z$-mass scale has been evaluated to a relative precision of $8 \cdot 10^{-3}$. The Fermi constant, parametrising the weak coupling strength, is known to $10^{-5}$ relative precision.

We perform global fits in two versions: the standard ("blue-band") fit makes use of all the available information except for the direct Higgs searches performed at LEP and the Tevatron; the complete fit uses also the constraints from the direct Higgs searches. Results in this paper are commonly derived for both types of fits.

Several improvements are expected from the LHC [16, 17]. The uncertainty on the $W$-boson and the top-quark masses should shrink to $1.8 \cdot 10^{-4}$ and $5.8 \cdot 10^{-3}$ respectively. In addition, the Higgs boson should be discovered leaving the SM without an unmeasured parameter (excluding here the massive neutrino sector, requiring at least nine additional parameters, which are however irrelevant for the results discussed in this paper). The primary focus of the global SM fit would then move from parameter estimation to the analysis of the goodness-of-fit with the goal to uncover inconsistencies between the model and the data, indicating the presence of new physics. Because the Higgs-boson mass enters only logarithmically in the loop corrections, a precision measurement is not required for this purpose. Dramatic improvements on SM observables are expected from the ILC [18]. The top and Higgs masses may be measured to a relative precision of about $1 \cdot 10^{-3}$, corresponding to absolute uncertainties of 0.2 GeV and 50 MeV, respectively. Running at lower energy with polarised beams, the $W$ mass could be determined to better than $7 \cdot 10^{-5}$ relative accuracy, and the weak mixing angle to a relative precision of $5 \cdot 10^{-5}$. Moreover, new precision measurements would enter the fit, namely the two-fermion cross section at higher energies and the triple gauge couplings of the electroweak gauge bosons, which are sensitive to models beyond the SM. Most importantly, however, both machines are directly sensitive to new phenomena and thus either provide additional constraints on fits of new physics models or – if the searches are successful – may completely alter our view of the physics at the terascale. The SM will then require extensions, the new parameters of which must be determined by a global fit, whose goodness must also be probed. To study the impact of the expected experimental improvements on the SM parameter determination, we perform fits under the assumption of various prospective setups (LHC, ILC, and ILC with GigaZ option).

As an example for a study beyond the SM we investigate models with an extended Higgs sector of two doublets (2HDM). We constrain the mass of the charged Higgs and the ratio of the vacuum expectation values of the two Higgs doublets using current measurements of observables from the $B$ and $K$ physics sectors and the most recent theoretical 2HDM predictions.

The paper is organised as follows. A disquisition of statistical considerations required for the interpretation of the fit results is given in Section 2. It is followed in Section 3 by an introduction to the Gfitter project and toolkit. The calculation of electroweak precision observables, the results of the global fit, and its perspectives are described in Section 4. Section 5 discusses results obtained for the Two Higgs Doublet Model. Finally, a collection of formulae used in the theoretical libraries of Gfitter is given in the appendix. We have chosen to give rather exhaustive
information here for the purpose of clarity and reproducibility of the results presented.

2 The Statistical Analysis

The fitting tasks are performed with the Gfitter toolkit described in Section 3. It features the minimisation of a test statistics and its interpretation using frequentist statistics. Confidence intervals and p-values are obtained with the use of toy Monte Carlo (MC) simulation or probabilistic approximations where mandatory due to resource limitations. This section introduces the three statistical analyses performed in the paper: (i) determination of SM parameters, (ii) probing the overall goodness of the SM, and (iii) probing SM extensions and determining its parameters. The SM part is represented by the global fit at the electroweak scale (Section 4), while as example for beyond SM physics we analyse an extension of the Higgs sector to two scalar doublets (Section 5). The statistical treatment of all three analyses relies on a likelihood function formed to measure the agreement between data and theory. The statistical discussion below follows in many aspects Refs. [19, 20] with additional input from [21, 22] and other statistical literature.

2.1 Model Parameters

We consider an analysis involving a set of \( N_{\text{exp}} \) measurements \((x_{\text{exp}})_i = 1 \ldots N_{\text{exp}}\), described by a corresponding set of theoretical expressions \((x_{\text{theo}})_i = 1 \ldots N_{\text{exp}}\). The theoretical expressions are functions of a set of \( N_{\text{mod}} \) model parameters \((y_{\text{mod}})_j = 1 \ldots N_{\text{mod}}\). Their precise definition is irrelevant for the present discussion besides the fact that:

- a subset of \((y_{\text{mod}})\) may be unconstrained parameters of the theory (e.g., the Higgs mass in the SM, if the results from the direct searches are not used);
- another subset of \((y_{\text{mod}})\) are theoretical parameters for which prior knowledge from measurements or calculations is available and used (e.g., the Z-boson mass and the hadronic vacuum polarisation contribution to the running electromagnetic coupling strength);
- the remaining \((y_{\text{mod}})\) parametrise theoretical uncertainties, which are based on hard-to-quantify educated guesswork (e.g., higher order QCD corrections to a truncated perturbative series).

It may occur that \(x_{\text{exp}}\) or \(y_{\text{mod}}\) parameters have statistical and theoretical errors, requiring a proper treatment for both of these. In the following we use the shorthand notations \(y_{\text{mod}}\) (\(x_{\text{exp}}, x_{\text{theo}}\)) to label both, sets of and individual parameters (measurements, theoretical expressions).

2.2 Likelihood Function

We adopt a least-squares like notation and define the test statistics

\[
\chi^2(y_{\text{mod}}) = -2 \ln L(y_{\text{mod}}),
\]

where the likelihood function, \(L\), is the product of two contributions

\[
L(y_{\text{mod}}) = L_{\text{exp}}(x_{\text{theo}}(y_{\text{mod}}) - x_{\text{exp}}) \cdot L_{\text{theo}}(y_{\text{mod}}).
\]
The experimental likelihood, $L_{\text{exp}}$, measures the agreement between $x_{\text{theo}}$ and $x_{\text{exp}}$, while the theoretical likelihood, $L_{\text{theo}}$, expresses prior knowledge of some of the $y_{\text{mod}}$ parameters. In most cases $L_{\text{exp}}$ incorporates well-behaved statistical errors as well as (mostly) non-statistical experimental systematic uncertainties. In some instances it may also include theoretical uncertainties and/or specific treatments that may account for inconsistent measurements. On the contrary, $L_{\text{theo}}$ relies on educated guesswork, akin to experimental systematic errors, but in most cases less well defined. The impact of (mostly strong interactions related) theoretical uncertainties and their treatment on the analysis may be strong, as it is the case for the global CKM fit [19, 20]. The statistical treatment $R\text{fit}$ [19, 20] (described below) is designed to deal with the problem of theoretical errors in a clear-cut and conservative manner. Evidently though, an ill-defined problem cannot be treated rigorously, and results that strongly depend on theory uncertainties must be interpreted with care. For the present analysis, by virtue of the large electroweak mass scale, purely theoretical errors are subdominant and controlled, so that the fit results are well behaved. Increasing experimental precision may alter this picture in the future.

### The Experimental Likelihood

The experimental component of the likelihood is given by the product

$$L_{\text{exp}}(x_{\text{theo}}(y_{\text{mod}}) - x_{\text{exp}}) = \prod_{i,j=1}^{N_{\text{exp}}} L_{\text{exp}}(i,j),$$

where the $N_{\text{exp}}$ individual likelihood components $L_{\text{exp}}(i,j)$ account for observables that may be independent or not. The model predictions of the observables depend on a subset of the $y_{\text{mod}}$ parameters, and are used to constrain those. Ideally, all likelihood components are independent (i.e., $L_{\text{exp}}(i,j) = 0$ for $i \neq j$) Gaussian functions, each with a standard deviation estimating the experimental statistical uncertainty.\(^1\) In practice, however, one has to deal with correlated measurements and with additional experimental and theoretical systematic uncertainties. In accordance with the approach adopted by most published analyses, experimental systematic errors are assumed to express Gaussian standard deviations, so that different systematic errors can be added in quadrature.\(^2\) Theoretical errors are treated according to the $R\text{fit}$ scheme described below.

### The Theoretical Likelihood

The theoretical component of the likelihood is given by the product

$$L_{\text{theo}}(y_{\text{mod}}) = \prod_{i=1}^{N_{\text{mod}}} L_{\text{theo}}(i).$$

\(^1\) The fitting procedure described in Section 2.3 uses $\chi^2$ minimisation to obtain the best match between a test hypothesis, represented by a certain parameter set, and the data. This requires the use of expected experimental errors corresponding to the test hypothesis in the experimental likelihood, rather than the measured experimental errors. However, the expected experimental errors are usually not available for all possible test hypotheses, and the measured experimental errors are used instead. This may be a reasonable approximation for test values in close vicinity of the measured experimental results. Nonetheless, one should expect that for regions that are strongly disfavoured by the likelihood estimator the statistical analysis is less precise, so that large deviations in terms of “sigmas” must be interpreted with care. We shall revisit this point in Section 4.2.2 when including results from the direct searches for the Higgs boson in the fit.

\(^2\) This introduces a Bayesian flavour to the statistical analysis.
2.3 Parameter Estimation

The individual components $L_{\text{theo}}(i)$ can be constant everywhere in case of no a-priori information, be bound, or may express a probabilistic function when such information is reliably available. Ideally, one should incorporate in $L_{\text{exp}}$ measurements (or equivalent determinations such as Lattice gauge theory, provided well-controlled theoretical assumptions are made) from which constraints on the $y_{\text{mod}}$ parameters can be derived. If such constraints are not available, or if a component has been explicitly introduced to parametrise theoretical uncertainty, the $L_{\text{theo}}(i)$ components must be incorporated by hand in Eq. (4). They are statistically ill-defined and can hardly be treated as probability density functions.

In the range fit approach, $R$fit, it is proposed that the theoretical likelihoods $L_{\text{theo}}(i)$ do not contribute to the $\chi^2$ of the fit when the corresponding $y_{\text{mod}}$ parameters take values within allowed ranges denoted $[y_{\text{mod}}]$. Usually these ranges are identified with the intervals $[\bar{y}_{\text{mod}} - \sigma_{\text{theo}}, \bar{y}_{\text{mod}} + \sigma_{\text{theo}}]$, where $\bar{y}_{\text{mod}}$ is a best-guess value, and $\sigma_{\text{theo}}$ is the theoretical systematic error assigned to $y_{\text{mod}}$. Hence all allowed $y_{\text{mod}}$ values are treated on equal footing, irrespective of how close they are to the edges of the allowed range. Instances where even only one of the $y_{\text{mod}}$ parameters lies outside its nominal range are not considered. This is the unique assumption made in the $R$fit scheme: $y_{\text{mod}}$ parameters for which a-priori information exists are bound to remain within predefined allowed ranges. The $R$fit scheme departs from a perfect frequentist analysis only because the allowed ranges $[y_{\text{mod}}]$ do not always extend to the whole physical space. This minimal assumption, is nevertheless a strong constraint: all the results obtained should be understood as valid only if all the assumed allowed ranges contain the true values of their $y_{\text{mod}}$ parameters. Because there is in general no guarantee for it being the case, a certain arbitrariness of the results remains and must be kept in mind.

Although in general range errors do not need to be of theoretical origin, but could as well parametrise hard-to-assess experimental systematics, or set physical boundaries, we will collectively employ the term “theoretical (or theory) errors” to specify range errors throughout this paper.

### 2.3 Parameter Estimation

When estimating model parameters one is not interested in the quality of the agreement between data and the theory as a whole. Rather, taking for granted that the theory is correct, one is only interested in the quality of the agreement between data and various realisations (models) of the theory, specified by distinct sets of $y_{\text{mod}}$ values. In the following we denote $\chi^2_{\text{min};y_{\text{mod}}}$ the absolute minimum value of the $\chi^2$ function of Eq. (1), obtained when letting all the $y_{\text{mod}}$ parameters free to vary within their respective bounds, with a fit converging at the solution $\hat{y}_{\text{mod}}$. One now attempts to estimate confidence intervals for the complete $y_{\text{mod}}$ set. This implies the use of the offset-corrected test statistics

$$
\Delta \chi^2(y_{\text{mod}}) = \chi^2(y_{\text{mod}}) - \chi^2_{\text{min};y_{\text{mod}}},
$$

where $\chi^2(y_{\text{mod}})$ is the $\chi^2$ for a given set of model parameters $y_{\text{mod}}$. Equation (5) represents the logarithm of a profile likelihood. The minimum value $\Delta \chi^2(\hat{y}_{\text{mod}})$ is zero, by construction. This

---

3Some $y_{\text{mod}}$ parameters do not have any a-priori information and are hence fully unbound in the fit.

4If a theoretical parameter is bound to an allowed range, and if this range is narrower than what the fit would yield as constraint for the parameter if let free to float, the best fit value of this (bound) parameter usually occurs on the edge of the allowed range. A modification of this range will thus have immediate consequences for the central values of the fit.

5The application of the $R$fit scheme in presence of theoretical uncertainties may lead to a non-unique $\{\hat{y}_{\text{mod}}\}$ solution space.
ensures that, consistent with the assumption that the model is correct, exclusion confidence levels (CL) equal to zero are obtained when exploring the \( y_{\text{mod}} \) space.

In general, the \( y_{\text{mod}} \) parameters in Eq. (5) are divided into relevant and irrelevant ones. The relevant parameters (denoted \( a \)) are scanned for estimation purposes, whereas the irrelevant ones (the nuisance parameters \( \mu \)) are adjusted such that \( \Delta \chi^2(a, \mu) \) is at a minimum for \( \mu = \hat{\mu} \). Since in frequentist statistics one cannot determine probabilities for certain \( a \) values to be true, one must derive exclusion CLs. The goal is therefore to set exclusion CLs in the \( a \) space irrespective of the \( \mu \) values.

A necessary condition is that the CL constructed from \( \Delta \chi^2(y_{\text{mod}}) \) provides sufficient coverage, that is, the CL interval for a parameter under consideration covers the true parameter value with a frequency of at least 1 − CL if the measurement were repeated many times. For a Gaussian problem, the test statistics follows a \( \chi^2 \) distribution [23] and one finds

\[
1 - \text{CL}(a, \hat{\mu}) = \text{Prob}(\Delta \chi^2(a, \hat{\mu}), \text{dim}[a]), \tag{6}
\]

where \text{dim}[a] is the dimension of the \( a \) space, which is the number of degrees of freedom\(^6\) of the offset-corrected \( \Delta \chi^2 \). Here the probability density distribution of \( \Delta \chi^2 \) is independent of \( \mu \). In a non-Gaussian case the CL interval for \( a \) must be evaluated with toy MC simulation for any possible set of true \( \mu \) values using, e.g., a Neyman construction [24] with likelihood-ratio ordering [25, 26].\(^7\) One may then choose for each \( a \) the set of \( \mu \) that gives the smallest CL(\( a \)). This “supremum” approach [21] (also described in Ref. [22] with however a somewhat different meaning) provides the most conservative result, which however overcovers in general. (Note also that the approach depends on the ordering algorithm used [27]). It may lead to the paradoxical situation that \( \mu \) values excluded by the data may be chosen as the true set to determine CL(\( a \)).

As a modification to this scheme, one could only consider \( \mu \) values that are within predefined \( \Delta \chi^2(a, \mu) \) bounds, thus guaranteeing a minimum compatibility with the data [28, 29]. A vast literature on this topic is available (see PhyStat conference proceedings and, e.g., Ref. [22]), mostly attempting to prescribe a limitation of the \( \mu \) space while maintaining good coverage properties.\(^8\) We point out that the naive “plugin” approach that consists of using the set of \( \hat{\mu} \) that minimises \( \Delta \chi^2(a, \hat{\mu}) \) in the fit to estimate the true \( \mu \) is incorrect in general (it is trivially correct if the problem is strictly Gaussian, as then the \( \Delta \chi^2 \) distribution is \( \mu \)-independent). It may lead to serious undercoverage if the \( \Delta \chi^2(a, \mu) \) frequency distribution is strongly dependent on \( \mu \) (cf. the analysis of the CKM phase \( \gamma \) [21]).

As a shortcut to avoid the technically challenging full Neyman construction in presence of nuisance parameters, one may choose a probabilistic interpretation of the profile likelihood \( \mathcal{L}(a, \hat{\mu}) \) versus \( a \), which corresponds to a MINOS [30] parameter scan. Simple tests suggest

\(^6\) Note that the effective number of degrees of freedom may not always be equal to the dimension of the \( a \) space. For example, if \text{dim}[a] = 2 but a single observable \( \mathcal{O} = f(a) \) is scanned in \( a \), only one of the two dimensions of \( a \) is independent, while the other can be derived via \( \mathcal{O} \) so that the effective \text{dim}[a] to be used here is one [20]. Similarly, the available observables may only constrain one of the two dimensions of \( a \). Again, the effective dimension to be used in Eq. (6) would be one. Intermediate cases, mixing strong and weak constraints in different dimensions of \( a \) may lead to an ill-posed situation, which can only be resolved by means of a full toy MC analysis. Such an analysis is performed at some instances in this paper (see in particular Section 5.2.2 for the two-dimensional case).

\(^7\) An ordering scheme is required because the construction of a Neyman CL belt is not unique. It depends on the definition of the test statistics used.

\(^8\) We recall here the reserve expressed in Footnote 1 on page 4 affecting the accuracy of any approach: the dependence of the measured errors on the outcome of the observables (determined by \( a \) and \( \hat{\mu} \)) – if significant – must be taken into account.
satisfying coverage properties of the profile likelihood scan (see, e.g., [31–33]). Mainly because of its simplicity this assumption will be adopted for most (though not all) of the results presented in this paper.

### 2.4 Probing the Standard Model

By construction, the parameter estimation via the offset-corrected $\Delta \chi^2$ is unable to detect whether the SM fails to describe the data. This is because Eq. (5) wipes out the information contained in $\chi^2_{\text{min}; \hat{y}_{\text{mod}}}$. This value is a test statistics for the best possible agreement between data and theory. The agreement can be quantified by the p-value $P(\chi^2_{\text{min}} \geq \chi^2_{\text{min}; \hat{y}_{\text{mod}}}|\text{SM})$, which is the tail probability to observe a test statistics value as large as or larger than $\chi^2_{\text{min}; \hat{y}_{\text{mod}}}$, if the SM is the theory underlying the data. It hence quantifies the probability of wrongly rejecting the SM hypothesis. In a Gaussian case, $\chi^2_{\text{min}; \hat{y}_{\text{mod}}}$ can be readily turned into a p-value via $\text{Prob}(\chi^2_{\text{min}; \hat{y}_{\text{mod}}}, n_{\text{dof}})$.

In presence of non-Gaussian effects, a toy MC simulation must be performed. Again, a full frequentist analysis requires the scan of all possible (or “likely”) true nuisance parameters, followed by toy MC studies to derive the corresponding p-values. Chosen is the set of true $\hat{y}_{\text{mod}}$ that maximises $P(\chi^2_{\text{min}; \hat{y}_{\text{mod}}}|\text{SM})$, where here exact coverage is guaranteed by construction (note that in this phase no explicit parameter determination is performed so that all $y_{\text{mod}}$ are nuisance parameters).

Such a goodness-of-fit test may not be the most sensitive manner to uncover physics beyond the SM (BSM). If the number of degrees of freedom is large in the global fit, and if observables that are sensitive to the BSM physics are mixed with insensitive ones, the fluctuations in the latter observables dilute the information contained in the global p-value (or deficiencies in the SM description may fake presence of new physics). It is therefore mandatory to also probe specific BSM scenarios.

### 2.5 Probing New Physics

If the above analysis establishes that the SM cannot accommodate the data, that is, the p-value is smaller than some critical value, the next step is to probe the BSM physics revealed by the observed discrepancy. The goal is akin to the determination of the SM parameters: it is to measure new sets of physical parameters $\{y_{\text{NP}}\}$ that complement the $\hat{y}_{\text{mod}}$ SM parameters. The treatment is identical to the one of Section 2.3, using $a = \{y_{\text{NP}}\}$. Even if the SM cannot be said to be in significant disagreement with the data, the estimation of $y_{\text{NP}}$ remains interesting because the most sensitive observables, and the precision to be aimed at for their determination can only be derived by this type of analysis. Moreover, the specific analysis might be able to faster detect the first signs of a discrepancy between data and the SM if the theoretical extension used in the analysis turns out to be the right one.

---

9 The corresponding ROOT function is TMath::Prob(...).
10 This problem is similar to those occurring in goodness-of-fit (GoF) tests in experimental maximum-likelihood analyses. If, for instance, the data sample with respect to which a likelihood analysis is performed is dominated by background events with a small but significant signal excess a successful global GoF test would only reveal agreement with the background model and say little about the signal. Similarly, a small p-value for the null hypothesis may reflect problems in the background description rather than an excess of signal events. A possible remedy here would be to restrict the GoF test to signal-like events, or more specifically, to test the GoF in all likelihood bins independently.
The Gfitter Package

The generic fitting package Gfitter comprises a statistical framework for model testing and parameter estimation problems. It is specifically designed to provide a modular environment for complex fitting tasks, such as the global SM fit to electroweak precision data, and fits beyond the SM. Gfitter is also a convenient framework for averaging problems, ranging from simple weighted means using or not correlated input data, to more involved problems with non-Gaussian PDFs and/or common systematic errors, requiring or not consistent rescaling due to parameter interdependencies.

Software

The Gfitter package [34] consists of abstracted object-oriented code in C++, relying on ROOT functionality [10]. The core fitting code and the physics content are organised in separate packages, each physics model package can be invoked as a plugin to the framework. The user interfaces Gfitter through data cards in XML format, where all the input data and driving options are defined. The fits are run alternatively as ROOT macros or executables, interactively or in a batch system.

Gfitter Parameters and Theories

Gfitter defines only a single data container, denoted parameter, which can have three distinct manifestations according to its use case:

(A) Measurements $x_{\text{exp}}$ that are predicted by the model (e.g., $W$ mass in the SM): parameters of this type are not varied in the fit, but contribute to the log-likelihood function through comparison between the model prediction and the corresponding measurement.

(B) Model parameters $y_{\text{mod}}$ that are not predicted by the theory but for which a direct measurement exists (e.g., top mass in the SM): parameters of this type are varied in the fit, and they contribute to the log-likelihood function through comparison between the fit parameter value and the corresponding measurement.

(C) Model Parameters $y_{\text{mod}}$ that are not predicted by the theory and for which no direct measurement exist (e.g., Higgs mass in the SM), or which parametrise theoretical uncertainties according to the $R$fit prescription (cf. Section 2.2): parameters of this type are varied freely in the fit within bounds (if exist), and they do not contribute themselves to the log-likelihood function.

A parameter is uniquely defined via a name (and optionally an alias to allow the user to declare several correlated measurements of the same parameter, and to design theoretical predictions in a polymorph class hierarchy) in the data card, and stored in a global parameter container. These parameters are objects (of the $GParameter$ class) that cannot be destroyed nor be recreated. Upon creation of a parameter, Gfitter searches automatically in the physics libraries for a corresponding theory (an object of the $GTheory$ class), identified through the name of the parameter. If a theory is found, the corresponding class object is instantiated\footnote{A $GTheory$ can depend on auxiliary theory objects (derived from $GTheory$) that are used to outsource complex computation tasks. Caching of results from repetitive calculations also benefits from outsourcing.} and the parameter

\footnote{A $GTheory$ can depend on auxiliary theory objects (derived from $GTheory$) that are used to outsource complex computation tasks. Caching of results from repetitive calculations also benefits from outsourcing.}
is categorised as of type (A); if no theory is found, it is of type (B) or (C) depending on the presence of a measurement in the data card. The categorisation of parameters is performed automatically by Gfitter maintaining full transparency for the user.

Parameter Errors, Ranges, Correlations and Rescaling

Gfitter distinguishes three types of errors: normal errors following a Gaussian distribution describing statistical and experimental systematic errors, a user-defined log-likelihood functions including statistical and systematic uncertainties, and allowed ranges describing physical limits or hard-to-assess systematic errors (mostly of theoretical origin). All errors can be asymmetric with respect to the central values given. All parameters may have combinations of Gaussian and range errors (but only a single user-defined likelihood function). Parameters of type (A) and (B) do not contribute to the log-likelihood functions if the theory prediction or floating parameter value is compatible with the central value of the parameter within the ranges of the theoretical errors attributed to the parameter (cf. Section 2.1 concerning the implications of the term “theoretical error”). Only beyond these ranges, a Gaussian parabolic contribution to the log-likelihood function occurs. For example, the combined log-likelihood function of a parameter with central value $x_0$, positive (negative) Gaussian error $\sigma^{+}\text{Gauss}$ ($\sigma^{-}\text{Gauss}$), and positive (negative) theoretical error $\sigma^{+}\text{theo}$ ($\sigma^{-}\text{theo}$), for a given set of $y_{\text{mod}}$ parameters and theoretical prediction $f(y_{\text{mod}})$ reads

$$-2\log L(y_{\text{mod}}) = \begin{cases} 
0, & \text{if: } -\sigma^{-}\text{theo} \leq f(y_{\text{mod}}) - x_0 \leq \sigma^{+}\text{theo}, \\
\left(\frac{f(y_{\text{mod}}) - (x_0 + \sigma^{+}\text{theo})}{\sigma^{+}\text{Gauss}}\right)^2, & \text{if: } f(y_{\text{mod}}) - x_0 > \sigma^{+}\text{theo}, \\
\left(\frac{f(y_{\text{mod}}) - (x_0 - \sigma^{-}\text{theo})}{\sigma^{-}\text{Gauss}}\right)^2, & \text{if: } x_0 - f(y_{\text{mod}}) > \sigma^{-}\text{theo}.
\end{cases}$$ (7)

Parameters of type (C) vary freely within the ranges set by the theoretical errors if available, or are unbound otherwise.

Parameters can have correlation coefficients identified and set in the data card via the parameter names (and alias if any). These correlations are taken into account in the log-likelihood test statistics as well as for the creation of toy MC experiments.

It is possible to introduce dependencies among parameters, which can be used to parametrise correlations due to common systematic errors, or to rescale parameter values and errors with newly available results for parameters on which other parameters depend. For example, in the global SM fit the experimental value used of the parameter $\Delta\alpha^{(5)}_{\text{had}}(M^{2}_{Z})$ depends on $\alpha_s(M^{2}_{Z})$. The value for $\alpha_s(M^{2}_{Z})$ used when evaluating $\Delta\alpha^{(5)}_{\text{had}}(M^{2}_{Z})$ may have been updated in the meantime, or may be updated in each fit step, which leads to a (not necessarily linear) shift of $\Delta\alpha^{(5)}_{\text{had}}(M^{2}_{Z})$ and also to a reduced systematic error (for details see Footnote 16 on page 18). The rescaling mechanism of Gfitter allows to automatically account for arbitrary functional interdependencies between an arbitrary number of parameters.

---

\textsuperscript{12} Measurement results can be given as central value and Gaussian (possibly asymmetric) and/or theoretical errors, or as a user-defined log-likelihood function encoded in ROOT objects (\textit{e.g.} histograms, graphs or functions).
Caching

An important feature of Gfitter is the possibility to cache computation results between fit steps. Each parameter holds pointers to the theory objects that depend on it, and the theories keep track of all auxiliary theory objects they depend on. Upon computation of the log-likelihood function in a new fit step, only those theories (or part of theories) that depend on modified parameters (with respect to the previous fit step) are recomputed. More importantly, time intensive calculations performed by auxiliary theories that are shared among several theories are made only once per fit step. The gain in CPU time of this caching mechanism is substantial, and can reach orders of magnitudes in many-parameter fitting problems.

Fitting

The parameter fitting is transparent with respect to the fitter implementation, which by default uses TMinuit [30], but which is extensible via the driving card to the more involved global minima finders Genetic Algorithm and Simulated Annealing, implemented in the ROOT package TMVA [35].

Parameter Scans and Contours

Gfitter offers the possibility to study the behaviour of the log-likelihood test statistics as a function of one or two parameters by one- or two-dimensional scans, respectively. If a parameter is of type (A), penalty contributions are added to the log-likelihood test statistics forcing the fit to yield the parameter value under study. In addition, two-dimensional contour regions of the test statistics can be computed using the corresponding TMinuit functionality.

Toy Monte Carlo Analyses

Gfitter offers the possibility to perform toy Monte Carlo (MC) analyses repeating the minimisation step for input parameter values that are randomly generated around expectation values according to specified errors and correlations. For each MC experiment the fit results are recorded allowing a statistical analysis, e.g., the determination of a p-value and an overall goodness-of-fit probability. All parameter scans can be optionally performed that way, as opposed to using a Gaussian approximation to estimate the p-value for a given scan point (manifestation of true values).

4 The Standard Model Fit to Electroweak Precision Data

In recent particle physics history, coined by the success of the electroweak unification and Quantum Chromodynamics (QCD), fits to experimental precision data have substantially contributed to our knowledge of the Standard Model (SM). The first application of global fits to electroweak data has been performed by the LEP electroweak working group [36] in the last decade of the 20th century, unifying LEP and SLD precision data. The primary results of these fits were a prediction of the top-quark mass (today’s fit precision $\simeq 9$ GeV) prior to its discovery, an accurate
and theoretically well controlled determination of the strong coupling constant at the $Z$-mass scale (today available at the 3NLO level [14]), and a logarithmic constraint on the Higgs mass establishing that the SM Higgs must be light. Other areas related to particle physics where global fits are performed are neutrino oscillation [37], leading to constraints on mixing parameters and mass hierarchies, flavour physics, with constraints on the parameters of the quark-flavour mixing (CKM) matrix and related quantities [19, 38], and cosmology [39], leading to a large number of phenomenological results such as the universe’s curvature, the relic matter and energy density, neutrino masses and the age of the universe. Global fits also exist for models beyond the SM such as Supersymmetry [40, 41] with however yet insufficient high-energy data for successfully constraining the parameters of even a minimal model so that simplifications are in order.

We emphasise that the goal of such fits is twofold (cf. Section 2): (i) the determination of the free model parameters, and (ii) a goodness-of-fit test measuring the agreement between model and data after fit convergence. This latter goal can be only achieved if the model is overconstrained by the available measurements. The situation is particularly favourable in the CKM sector, where the primary goal of experiments and phenomenological analysis has been moved from CKM parameter determination to the detection of new physics via inconsistencies in the CKM phase determination. The relatively young field of neutrino oscillation measurements on the contrary does not yet provide significant overconstraints of the neutrino flavour mixing matrix.

In the following we revisit the global electroweak fit at the $Z$-mass scale using the Gfitter package. We recall the relevant observables, their SM predictions, perform fits under various conditions, and discuss the results.

### 4.1 Formalism and Observables

The formal analysis of this section is placed within the framework of the SM. The electroweak fit focuses on the parameters directly related to the $Z$ and $W$ boson properties, and to radiative corrections to these, providing the sensitivity to heavy particles like the top quark and the Higgs boson. The floating parameters of the fit are the Higgs and $Z$-boson masses, the $c$, $b$, and $t$-quark masses, as well as the electromagnetic and strong coupling strengths at the $Z$ pole. Most of these parameters are also directly constrained by measurements included in the fit.

We have put emphasis on the completeness of the information given in this paper, with a large part of the relevant formulae quoted in the main text and the appendices. Readers seeking for a more pedagogical introduction are referred to the many excellent reviews on this and related topics (see, e.g., Refs. [13, 42–44]). Section 4.1.1 provides a formal introduction of tree-level relations, and quantum loop corrections sensitive to particles heavier than the $Z$. The observables used in the global fit and their SM predictions are summarised in Section 4.1.2 and Section 4.1.3 respectively. Theoretical uncertainties are discussed in Section 4.1.4.
4.1.1 Standard Model Tree-Level Relations and Radiative Corrections

The tree-level vector and axial-vector couplings occurring in the $Z$ boson to fermion-antifermion vertex $\overrightarrow{f}\gamma_{\mu}(g_{V,f}^{(0)} + g_{A,f}^{(0)}\gamma_{5})fZ_{\mu}$ are given by\textsuperscript{13}

\begin{align}
    g_{V,f}^{(0)} &\equiv g_{L,f}^{(0)} + g_{R,f}^{(0)} = I_{3}^{f} - 2Q^{f}\sin^{2}\theta_{W}, &\text{(8)}
    \\
    g_{A,f}^{(0)} &\equiv g_{L,f}^{(0)} - g_{R,f}^{(0)} = I_{3}^{f}, &\text{(9)}
\end{align}

where $g_{L(R),f}^{(0)}$ are the left-handed (right-handed) fermion couplings, and $Q^{f}$ and $I_{3}^{f}$ are respectively the charge and the third component of the weak isospin. In the (minimal) SM, containing only one Higgs doublet, the weak mixing angle is defined by

$$
\sin^{2}\theta_{W} = 1 - \frac{M_{W}^{2}}{M_{Z}^{2}}.
$$

Electroweak radiative corrections modify these relations, leading to an effective weak mixing angle and effective couplings

\begin{align}
    \sin^{2}\theta_{W}^{\text{eff}} &= \kappa_{Z}^{f}\sin^{2}\theta_{W}, &\text{(11)}
    \\
    g_{V,f} &= \sqrt{\rho_{Z}^{f}}(I_{3}^{f} - 2Q^{f}\sin^{2}\theta_{W}^{\text{eff}}), &\text{(12)}
    \\
    g_{A,f} &= \sqrt{\rho_{Z}^{f}}I_{3}^{f}, &\text{(13)}
\end{align}

where $\kappa_{Z}^{f}$ and $\rho_{Z}^{f}$ are form factors absorbing the radiative corrections. They are given in Eqs. (59) and (60) of Appendix A.3. Due to non-zero absorptive parts in the self-energy and vertex correction diagrams, the effective couplings and the form factors are complex quantities. The observable effective mixing angle is given by the real parts of the couplings

$$
\frac{\text{Re}(g_{V,f})}{\text{Re}(g_{A,f})} = 1 - 4|Q^{f}|\sin^{2}\theta_{W}^{\text{eff}}.
$$

Electroweak unification leads to a relation between weak and electromagnetic couplings, which at tree level reads

$$
G_{F} = \frac{\pi\alpha}{\sqrt{2}(M_{W}^{(0)2})\left(1 - \left(M_{W}^{(0)2}/M_{Z}^{2}\right)^{2}\right)}. &\text{(15)}
$$

Radiative corrections are parametrised by multiplying the r.h.s. of Eq. (15) with the form factor $(1 - \Delta r)^{-1}$. Using Eq. (10) and resolving for $M_{W}$ gives

$$
M_{W}^{2} = \frac{M_{Z}^{2}}{2}\left(1 + \sqrt{1 - \frac{\sqrt{8}\pi\alpha(1 - \Delta r)}{G_{F}M_{Z}^{2}}}\right). &\text{(16)}
$$

The form factors $\rho_{Z}^{f}$, $\kappa_{Z}^{f}$ and $\Delta r$ depend nearly quadratically on $m_{t}$ and logarithmically on $M_{H}$. They have been calculated including two-loop corrections in the on-shell renormalisation scheme (OMS) [45–47]. The relevant formulae used in this analysis are summarised in Appendix A.3. Since $\Delta r$ also depends on $M_{W}$ an iterative method is needed to solve Eq. (16). The calculation

\textsuperscript{13}Throughout this paper the superscript ’(0)’ is used to label tree-level quantities.
of $M_W$ has been performed including the complete one-loop correction, two-loop and three-loop QCD corrections of order $O(\alpha \alpha_s)$ and $O(\alpha_s^2)$, fermionic and bosonic two-loop electroweak corrections of order $O(\alpha^2)$, and the leading $O(G_F^2 \alpha_s m_t^2)$ and $O(G_W^2 m_t^2)$ three-loop contributions [11, 12]. Four-loop QCD corrections have been calculated for the $\rho$-parameter [48, 49]. Since they affect the $W$ mass by 2 MeV only, they have been neglected in this work.

For the SM prediction of $M_W$ we use the parametrised formula [11]

$$M_W = M_W^{\text{ini}} - c_1 \, dH - c_2 \, dH^2 + c_3 \, dH^4 + c_4 \, (dh - 1) - c_5 \, d\alpha + c_6 \, dt - c_7 \, dt^2 - c_8 \, dH \, dt + c_9 \, dh \, dt - c_{10} \, d\alpha_s + c_{11} \, dZ,$$

(17)

with

$$dH = \ln \left( \frac{M_H}{100 \text{ GeV}} \right), \quad dh = \left( \frac{M_H}{100 \text{ GeV}} \right)^2, \quad dt = \left( \frac{m_t}{174.3 \text{ GeV}} \right)^2 - 1,$$

$$dZ = \frac{M_Z}{91.1875 \text{ GeV}} - 1, \quad d\alpha = \frac{\Delta \alpha(M_Z^2)}{0.05907} - 1, \quad d\alpha_s = \frac{\alpha_s(M_Z^2)}{0.119} - 1,$$

where here and below all masses are in units of GeV, and where $m_t$ is the top-quark pole mass, $M_Z$ and $M_H$ are the $Z$ and Higgs boson masses, $\Delta \alpha(M_Z^2)$ is the sum of the leptonic and hadronic contributions to the running QED coupling strength at $M_Z^2$ (cf. Appendix A.1), $\alpha_s(M_Z^2)$ is the running strong coupling constant at $M_Z^2$ (cf. Appendix A.2.1), and where the coefficients $M_W^{\text{ini}}, c_1, \ldots, c_{11}$ read

$$M_W^{\text{ini}} = 80.3799 \text{ GeV}, \quad c_1 = 0.05429 \text{ GeV}, \quad c_2 = 0.008939 \text{ GeV},$$

$$c_3 = 0.0000890 \text{ GeV}, \quad c_4 = 0.000161 \text{ GeV}, \quad c_5 = 1.070 \text{ GeV},$$

$$c_6 = 0.5256 \text{ GeV}, \quad c_7 = 0.0678 \text{ GeV}, \quad c_8 = 0.00179 \text{ GeV},$$

$$c_9 = 0.0000659 \text{ GeV}, \quad c_{10} = 0.0737 \text{ GeV}, \quad c_{11} = 114.9 \text{ GeV}.$$

The parametrisation reproduces the full result for $M_W$ to better than 0.5 MeV over the range 10 GeV $< M_H < 1$ TeV, if all parameters are within their expected (year 2003) 2σ intervals [11].

The effective weak mixing angle of charged leptons, $\sin^2 \theta^\ell_{\text{eff}}$, with $\ell = e, \mu, \tau$, has been computed [12] with the full electroweak and QCD one-loop and two-loop corrections, and the leading three-loop corrections of orders $O(G_F^2 \alpha_s m_t^2)$ and $O(G_W^2 m_t^2)$. The corresponding parametrisation formula reads

$$\sin^2 \theta^\ell_{\text{eff}} = s_0 + d_1 L_H + d_2 L_H^2 + d_3 L_H^3 + d_4 (\Delta_H^2 - 1) + d_5 \Delta_\alpha + d_6 \Delta_\ell + d_7 \Delta_\ell^2 + d_8 \Delta_\ell (\Delta_H - 1) + d_9 \Delta_\alpha_s + d_{10} \Delta_Z,$$

(18)

with

$$L_H = \ln \left( \frac{M_H}{100 \text{ GeV}} \right), \quad \Delta_H = \frac{M_H}{100 \text{ GeV}}, \quad \Delta_\alpha = \frac{\Delta \alpha(M_Z)}{0.05907} - 1,$$

$$\Delta_\ell = \left( \frac{m_t}{178.0 \text{ GeV}} \right)^2 - 1, \quad \Delta_\alpha_s = \frac{\alpha_s(M_Z^2)}{0.117} - 1, \quad \Delta_Z = \frac{M_Z}{91.1876 \text{ GeV}} - 1,$$

and the numerical values

$$s_0 = 0.2312527, \quad d_1 = 4.729 \cdot 10^{-4}, \quad d_2 = 2.07 \cdot 10^{-5},$$

$$d_3 = 3.85 \cdot 10^{-6}, \quad d_4 = -1.85 \cdot 10^{-6}, \quad d_5 = 0.0207,$$

$$d_6 = -0.002851, \quad d_7 = 1.82 \cdot 10^{-4}, \quad d_8 = -9.74 \cdot 10^{-6},$$

$$d_9 = 3.98 \cdot 10^{-4}, \quad d_{10} = -0.655.$$
Equation (18) reproduces the full expression with maximum (average) deviation of $4.5 \cdot 10^{-6}$ $(1.2 \cdot 10^{-6})$, if the Higgs-boson mass lies within $10 \text{ GeV} < M_H < 1 \text{ TeV}$, and if all parameters are within their expected (year 2003) $2\sigma$ intervals [12].

Assuming the beyond-two-loop corrections in Eq. (18) to be independent of light-quark and neutrino flavours, one can use the above result to also improve the two-loop prediction of $\sin^2 \theta^f_{\text{eff}}$ for the remaining fermions ($f = u, d, s, c$ and neutrinos) via the approximation [50]

$$\sin^2 \theta^f_{\text{eff}} = (\kappa_Z^f)_{(2\gamma)} \sin^2 \theta_W + \left( (\sin^2 \theta^f_{\text{eff}})_{(b2\gamma)} - (\kappa_Z^f)_{(2\gamma)} \sin^2 \theta_W \right),$$

(19)

where $(\kappa_Z^f)_{(2\gamma)}$ and $(\kappa_Z^f)_{(b2\gamma)}$ are calculated including the known 2-loop corrections (cf. Appendix A.3), $(\sin^2 \theta^f_{\text{eff}})_{(b2\gamma)}$ is the beyond-two-loop calculations of Eq. (18) and $\sin^2 \theta_W$ is calculated with Eq. (10) using Eq. (17). For bottom quarks, where this approximation is not valid because $b\bar{b}$ final states involve new topologies with additional top-quark propagators, we use Eq. (11) and the two-loop calculation of $\kappa_Z^f$.

### 4.1.2 Summary of Electroweak Observables

The following classes of observables are used in the fit.

- **Z resonance parameters:** Z mass and width, and total $e^+e^- \to Z \to \text{hadron production cross section (i.e., corrected for photon exchange contributions).**}

- **Partial Z cross sections:** Ratios of leptonic to hadronic, and heavy-flavour hadronic to total hadronic cross sections.

- **Neutral current couplings:** Effective weak mixing angle, and left-right and forward-backward asymmetries for universal leptons and heavy quarks.\(^{14}\)

- **W boson parameters:** W mass and width.

- **Higgs boson parameters:** Higgs mass.

- **Additional input parameters:** Heavy-flavour ($c, b, t$) quark masses (masses of lighter quarks and leptons are fixed to their world averages), QED and QCD coupling strengths at the $Z$-mass scale.

### 4.1.3 Theoretical Predictions of Electroweak Observables

Parity violation in neutral current reactions $e^+e^- \to j\bar{j}$ resulting from the different left and right-handed $Z$-boson couplings to fermions leads to fermion polarisation in the initial and final states and thus to observable asymmetry effects. They can be conveniently expressed by the asymmetry parameters

$$A_f = \frac{g_{L,f}^2 - g_{R,f}^2}{g_{L,f}^2 + g_{R,f}^2} = 2 \frac{g_{V,f}/g_{A,f}}{1 + (g_{V,f}/g_{A,f})^2},$$

(20)

where only the real parts of the couplings are considered as the asymmetries refer to pure $Z$ exchange. For instance, the forward-backward asymmetry $A_{FB}^B = (\sigma_{F,B}^0 - \sigma_{B,F}^0)/(\sigma_{F,B}^0 + \sigma_{B,F}^0)$.

\(^{14}\)Left-right and forward-backward asymmetries have been also measured for strange quarks, with however insufficient precision to be included here.
where the superscript ‘0’ indicates that the observed values have been corrected for radiative effects and photon exchange, can be determined from the asymmetry parameters (20) as follows

\[ A_{\text{FB}}^{0,f} = \frac{3}{4} A_e A_f. \]  

The \( A_f \) are obtained from Eqs. (20) and (14) using \( \sin^2 \theta_{\text{eff}}^f \) from the procedure described in the previous section.

Unlike the asymmetry parameters, the partial decay width \( \Gamma_f = \Gamma(Z \rightarrow f \bar{f}) \) is defined inclusively, i.e., it contains all real and virtual corrections such that the imaginary parts of the couplings must be taken into account. One thus has

\[ \Gamma_f = 4 N_c^{(f)} \Gamma_0 |\rho_Z^f| (I_f^2) \left( \frac{g_{V,f}^2}{g_{A,f}^2} \right) \left( R_V^f(M_Z^2) + R_A^f(M_Z^2) \right), \]  

where \( N_c^{(q)} = 1(3) \) is the colour factor, \( R_V^f(M_Z^2) \) and \( R_A^f(M_Z^2) \) are radiator functions (defined further below), and \( \Gamma_0 \) is given by

\[ \Gamma_0 = \frac{G_F M_Z^3}{24 \sqrt{2} \pi}. \]  

The \( \sin^2 \theta_{\text{eff}}^f \) term entering through the ratio of coupling constants in Eq. (22) is modified by the real-valued contribution \( I_f^2 \) resulting from the product of two imaginary parts of polarisation operators [6]

\[ \sin^2 \theta_{\text{eff}}^f \rightarrow \sin^2 \theta_{\text{eff}}^f + I_f^2, \]  

where

\[ I_f^2 = \alpha^2(M_Z^2) \frac{35}{18} \left( 1 - \frac{8}{3} \text{Re}(\kappa_f^Z) \sin^2 \theta_W \right). \]  

The full expression for the partial leptonic width reads [6]

\[ \Gamma_\ell = \Gamma_0 |\rho_Z^\ell| \sqrt{1 - \frac{4m_\ell^2}{M_Z^2}} \left[ 1 + \frac{2m_\ell^2}{M_Z^2} \left( \left( \frac{g_{V,\ell}}{g_{A,\ell}} \right)^2 + 1 \right) - \frac{6m_\ell^2}{M_Z^2} \right] \cdot \left( 1 + \frac{3 \alpha(M_Z^2)}{4 \pi} Q_\ell^2 \right), \]  

which includes effects from QED final state radiation. The partial widths for \( q\bar{q} \) final states, \( \Gamma_q \), involve radiator functions that describe the final state QED and QCD vector and axial-vector corrections for quarkonic decay modes. Furthermore, they contain QED \( \otimes \) QCD and finite quark-mass corrections. For the massless perturbative QCD correction, the most recent fourth-order result is used [14]. Explicit formulae for the radiator functions are given in Appendix A.4. The influence of non-factorisable EW \( \otimes \) QCD corrections, \( \Delta_{\text{EW/QCD}} \), that must be added to the width (22) for quark final states is small (less than \( 10^{-3} \)). They are assumed to be constant [51, 52], and take the values

\[ \Delta_{\text{EW/QCD}} = \begin{cases} -0.113 \text{ MeV for } u \text{ and } c \text{ quarks}, \\ -0.160 \text{ MeV for } d \text{ and } s \text{ quarks}, \\ -0.040 \text{ MeV for the } b \text{ quark}. \end{cases} \]  

The total \( Z \) width for three light neutrino generations obeys the sum

\[ \Gamma_Z = \Gamma_e + \Gamma_\mu + \Gamma_\tau + 3\Gamma_\nu + \Gamma_{\text{had}}, \]
where $\Gamma_{\text{had}} = \Gamma_u + \Gamma_d + \Gamma_c + \Gamma_s + \Gamma_b$ is the total hadronic $Z$ width. From these the improved tree-level total hadronic cross-section at the $Z$ pole is given by

$$\sigma^0_{\text{had}} = \frac{12\pi \Gamma_e \Gamma_{\text{had}}}{M_Z^2 \Gamma_Z^2}. \quad (29)$$

To reduce systematic uncertainties, the LEP experiments have determined the partial-$Z$-width ratios $R^0_\ell = \Gamma_{\text{had}}/\Gamma_\ell$ and $R^0_q = \Gamma_q/\Gamma_{\text{had}}$, which are used in the fit.

The computation of the $W$ boson width is similar to that of the $Z$ boson, but it is only known to one electroweak loop. The expression adopted in this analysis can be found in [53]. An improved, gauge-independent formulation exists [54], but the difference with respect to the gauge-dependent result is small (0.01%) compared to the current experimental error (3%).

The value of the QED coupling constant at the $Z$ pole is obtained using three-loop results for the leptonic contribution, and the most recent evaluation of the hadronic vacuum polarisation contribution for the five quarks lighter than $M_Z$. Perturbative QCD is used for the small top-quark contribution. The relevant formulae and references are given in Appendix A.1.

The evaluation of the running QCD coupling constant uses the known four-loop expansion of the QCD $\beta$-function, including three-loop matching at the quark-flavour thresholds (cf. Appendix A.2.1). The running of the $b$ and $c$ quark masses is obtained from the corresponding four-loop $\gamma$-function (cf. Appendix A.2.2). All running QCD quantities are evaluated in the modified minimal subtraction renormalisation scheme ($\overline{\text{MS}}$).

### 4.1.4 Theoretical Uncertainties

Within the $R$ fit scheme, theoretical errors based on educated guesswork are introduced via bound theoretical scale parameters in the fit, thus providing a consistent numerical treatment. For example, the effect from a truncated perturbative series is included by adding a deviation parameter, $\delta_{th}$, describing the varying perturbative prediction as a function of the contribution from the unknown terms. Leaving the deviation parameter floating within estimated ranges allows the fit to adjust it when scanning a parameter, such that the likelihood estimator is increased (thus improving the fit compatibility).

The uncertainties in the form factors $\rho_f^Z$ and $\kappa_f^Z$ are estimated using different renormalisation schemes, and the maximum variations found are assigned as theoretical errors. A detailed numerical study has been performed in [55] leading to the following real-valued relative theoretical errors

$$\delta_{th} \rho_f^Z / |1 - \rho_f^Z| \approx 5 \cdot 10^{-3}, \quad (30)$$

$$\delta_{th} \kappa_f^Z / |1 - \kappa_f^Z| \approx 5 \cdot 10^{-4}, \quad (31)$$

which vary somewhat depending on the fermion flavour. The corresponding absolute theoretical errors are around $2 \cdot 10^{-5}$ for both $\delta_{th} \rho_f^Z$ and $\delta_{th} \kappa_f^Z$ and are treated as fully correlated in the fit. These errors, albeit included, have a negligible effect on the fit results.

More important are theoretical uncertainties affecting directly the $M_W$ and $\sin^2 \theta^\ell_{\text{eff}}$ predictions. They arise from three dominant sources of unknown higher-order corrections [11, 12]: (i) $O(\alpha^2 \alpha_s)$ terms beyond the known contribution of $O(G_F^2 \alpha_s m_t^4)$, (ii) $O(\alpha^3)$ electroweak three-loop corrections, and (iii) $O(\alpha_s^3)$ QCD terms. The quadratic sums of the above corrections...
Global Standard Model Analysis

4.2 Global Standard Model Analysis

The last two decades have been prolificous in providing precision experimental data at the electroweak scale. Driven by measurements at LEP, SLC and the Tevatron, and significant theoretical progress, many phenomenological analyses have been performed, of which we re-examine below the global SM fit. The primary goal of this re-analysis is (i) to validate the new fitting toolkit Gfitter and its SM library with respect to earlier results [5–8], (ii) to include the results from the direct Higgs searches at LEP and the Tevatron in the global fit, (iii) to revisit the impact of theoretical uncertainties on the results, and (iv) to perform more complete statistical tests.

4.2.1 Floating Fit Parameters

The SM parameters relevant for the global electroweak analysis are the coupling constants of the electromagnetic (\(\alpha\)), weak (\(G_F\)) and strong interactions (\(\alpha_S\)), and the masses of the elementary bosons (\(M_\gamma, M_Z, M_W, M_H\)) and fermions (\(m_f \) with \(f = e, \mu, \tau, \nu_e, \nu_\mu, \nu_\tau, u, c, t, d, s, b\)), where neutrinos are taken to be massless. The fit simplifies with electroweak unification resulting in a massless photon and a relation between the \(W\) mass and the electromagnetic coupling \(\alpha\), the \(Z\) mass, and the weak coupling \(G_F\), according to Eq. (15). Further simplification of the fit arises from fixing parameters with insignificant uncertainties compared to the sensitivity of the fit.

- Compared to \(M_Z\) the masses of leptons and light quarks are small and/or sufficiently well known so that their uncertainties are negligible in the fit. They are fixed to their world average values [60]. Only the masses of the heavy quarks,\(^\text{15}\) \(m_c\), \(m_b\), and \(m_t\), are floating.

\(^{15}\text{In the analysis and throughout this paper we use the }\overline{\text{MS}}\text{ renormalised masses of the }c\text{ and }b\text{ quarks, }m_c(\overline{m_c})\text{ and }m_b(\overline{m_b}),\text{ at their proper scales. In the following they are denoted with }\overline{m_c}\text{ and }\overline{m_b},\text{ respectively.}\)

\[\delta_{\text{th}} M_W \approx 4 \text{ MeV},\]
\[\delta_{\text{th}} \sin^2 \theta_{\text{eff}} \approx 4.7 \cdot 10^{-5},\]

which are the theoretical ranges used in the fit. The empirical \(W\) mass parametrisation (17) is only valid for a relatively light Higgs boson, \(M_H \lesssim 300 \text{ GeV}\), for which the error introduced by the approximation is expected to be negligible [11]. For larger Higgs masses, the total theoretical error used is linearly increased up to \(\delta_{\text{th}} M_W = 6 \text{ MeV at } M_H = 1 \text{ TeV}\), which is a coarse estimate along the theoretical uncertainties given in [11].

Theoretical uncertainties affecting the top mass from non-perturbative colour-reconnection effects in the fragmentation process [56, 57] and due to ambiguities in the top-mass definition [58, 59] have been recently estimated to approximately 0.5 GeV each. The systematic error due to shower effects may be larger [56]. Especially the colour-reconnection and shower uncertainties, estimated by means of a toy model, need to be verified with experimental data and should be included in the top-mass result published by the experiments. Both errors have been neglected for the present analysis.

Other theoretical uncertainties are introduced via the evolution of the QED and QCD couplings and quark masses, and are discussed in Appendices A.1 and A.2.
in the fit while being constrained to their experimental values. The top mass uncertainty has the strongest impact on the fit.

- The weak coupling constant $G_F$ has been accurately determined through the measurement of the $\mu$ lifetime, giving $G_F = 1.16637(1) \times 10^{-5}$ GeV$^{-2}$ [60]. The parameter is fixed in the fit.

- The leptonic and top-quark vacuum polarisation contributions to the running of the electromagnetic coupling are precisely known or small. Only the hadronic contribution for the five lighter quarks, $\Delta\alpha_{\text{had}}^{(5)}(M_Z^2)$, adds significant uncertainties and replaces the electromagnetic coupling $\alpha(M_Z^2)$ as floating parameter in the fit (cf. Appendix A.1).

With the $R$fit treatment of theoretical uncertainties four deviation parameters are introduced in the fit. They vary freely within their corresponding error ranges (cf. Section 4.1.4). The theoretical uncertainties in the predictions of $M_W$ and $\sin^2\theta_{\text{eff}}$ are parametrised by $\delta_{\text{th}} M_W$ and $\delta_{\text{th}} \sin^2\theta_{\text{eff}}$. The form factors $\kappa^l_Z$ and $\rho^l_Z$ have theoretical errors $\delta_{\text{th}} \kappa^l_Z$ and $\delta_{\text{th}} \rho^l_Z$, which are treated as fully correlated in the fit.

In summary, the floating parameters in the global electroweak fit are the coupling parameters $\Delta\alpha_{\text{had}}^{(5)}(M_Z^2)$ and $\alpha_{\text{s}}(M_Z^2)$, the masses $M_Z$, $m_c$, $m_b$, $m_t$ and $M_H$, and four theoretical error parameters.

### 4.2.2 Input Data

A summary of the input data used in the fit is given in the second column of Table 1, and discussed below.

- The mass and width of the Z boson, the hadronic pole cross section $\sigma^0_{\text{had}}$, the partial widths ratio $R_0^l$, and the forward-backward asymmetries for leptons $A_{\text{FB}}^{0,\ell}$, have been determined by fits to the Z lineshape measured precisely at LEP (see [43] and references therein). Measurements of the $\tau$ polarisation at LEP [43] and the left-right asymmetry at SLC [43] have been used to determine the lepton asymmetry parameter $A_{\ell}$. The corresponding $c$ and $b$-quark asymmetry parameters $A_{c(b)}$, the forward-backward asymmetries $A_{\text{FB}}^{0, c(b)}$, and the widths ratios $R_0^c$ and $R_0^b$, have been measured at LEP and SLC [43]. In addition, the forward-backward charge asymmetry $(Q_{\text{FB}})$ measurement in inclusive hadronic events at LEP was used to directly determine the effective leptonic weak mixing angle $\sin^2\theta_{\text{eff}}$ [43]. The log-likelihood function used in the fit includes the linear correlation coefficients among the Z-lineshape and heavy-flavour observables given in Table 2.

- For the running quark masses $m_c$ and $m_b$, the world average values derived in [60] are used. The combined top-quark mass is taken from the Tevatron Electroweak Working Group [61].

- For the five-quark hadronic contribution to $\alpha(M_Z^2)$, the most recent phenomenological result is used [62] (see also the discussion in [63]). Its dependence on $\alpha_{\text{s}}(M_Z^2)$ requires a proper rescaling in the fit (cf. Section 3).\(^\text{16}\)

\(^{16}\) In [62] the light-quark hadronic contribution to $\alpha(M_Z^2)$ was found to be $\Delta\alpha_{\text{had}}^{(5)}(M_Z^2) = 0.02768 \pm 0.00022 \pm \ldots$

(**)Rescaled due to \(\alpha_s\) dependency.

Table 1: Input values and fit results for parameters of the global electroweak fit. The first and second columns list respectively the observables/parameters used in the fit, and their experimental values or phenomenological estimates (see text for references). The subscript “theo” labels theoretical error ranges. The third column indicates whether a parameter is floating in the fit. The fourth (fifth) column quotes the results of the standard (complete) fit not including (including) the constraints from the direct Higgs searches at LEP and Tevatron in the fit. In case of floating parameters the fit results are directly given, while for observables, the central values and errors are obtained by individual profile likelihood scans. The errors are derived from the \(\Delta\chi^2\) profile using a Gaussian approximation. The last column gives the fit results for each parameter without using the corresponding experimental constraint in the fit (indirect determination).

Table 2: Correlation matrices for observables determined by the $Z$ lineshape fit (left), and by heavy flavour analyses at the $Z$ pole (right) [43].

- The LEP and Tevatron results for the $W$ mass and width are respectively $M_W = (80.378 \pm 0.033)$ GeV, $\Gamma_W = (2.196 \pm 0.083)$ GeV [64], and $M_W = (80.432 \pm 0.039)$ GeV, $\Gamma_W = (2.056 \pm 0.062)$ GeV [65, 66]. Their weighted averages [65], quoted without the correlation coefficient between mass and width, are used in the fit (cf. Table 1). Since a modest correlation has insignificant impact on the fit results\(^{17}\) it is ignored in the following.

- The direct searches for the SM Higgs boson at LEP [67] and at the Tevatron [68, 69] use as test statistics the logarithmic form of a likelihood ratio, $-2\ln Q$, of the signal plus background ($s+b$) to the background-only ($b$) hypotheses. This choice guarantees $-2\ln Q = 0$ when there is no experimental sensitivity to a Higgs signal. The corresponding one-sided confidence levels $\text{CL}_{s+b}$ and $\text{CL}_b$ describe respectively the probabilities of upward and downward fluctuations of the test statistics in presence and absence of a signal ($\text{CL}_b$ is thus the probability of a false discovery). They are derived using toy MC experiments.\(^{18}\)

In the modified frequentist approach [70–72], a hypothesis is considered excluded at 95% CL if the ratio $\text{CL}_b = \text{CL}_{s+b}/\text{CL}_b$ is equal or lower than 0.05. The use of $\text{CL}_b$ leads to a more conservative limit [67] than the (usual) approach based on $\text{CL}_{s+b}$.\(^{19}\) Using this method the combination of LEP searches [67] has set the lower limit $M_H > 114.4$ GeV at 95% CL. For the Tevatron combination [68, 69], ratios of the 95% CL cross section limits to the SM Higgs boson production cross section as a function of the Higgs mass are derived, exhibiting a minimum of 1.0 at $M_H = 170$ GeV. The LEP Higgs Working Group provided the observed and expected $-2\ln Q$ curves and the corresponding values of the aforementioned confidence levels up to $M_H = 120$ GeV. The Tevatron New Phenomena and Higgs Working

---

0.00002, where the second error singles out the uncertainty from the strong coupling constant for which $\alpha_s(M^2_Z) = 0.118 \pm 0.003$ was used. Linear rescaling leads to the modified central value $\Delta\alpha^0_{\text{had}}(M^2_Z) = 0.02768 + 0.00002 \cdot (\alpha_s(M^2_Z))_{\text{fit}} - 0.118)/0.003$. Since $\alpha_s(M^2_Z)$ is a free fit parameter and has no uncertainty in a certain fit step the error on $\Delta\alpha^0_{\text{had}}(M^2_Z)$ used in the log-likelihood function does no longer include the contribution from $\alpha_s(M^2_Z)$, but the corresponding variation is included in the rescaling of the central value only.

\(^{17}\)A correlation of 0.2 between $W$ mass and width was reported for the Tevatron Run-I results [43]. Assuming the same correlation for the LEP and Tevatron combined values of $W$ mass and width leads to an increase of the $\chi^2_{\text{min}}$ of the standard fit (complete fit) by 0.09 (0.23). In the complete fit the central value of the Higgs mass estimate is unchanged (only the +1σ bound slightly reduces by 0.6 GeV), whereas a downward shift of 1.1 GeV of the central value is observed for the standard fit.

\(^{18}\)For a counting experiment with $N$ observed events and $N_s$ ($N_s \gg N_b$) expected signal (background) events, one has $-\ln Q = N_s - N \ln(N_s/N_b + 1) \approx N_s(1 - N/N_b)$, leading to small $-\ln Q$ values for large $N$ (signal-like) and large $-\ln Q$ values for small $N$ (background-like). For sufficiently large $N_s + N_b$, the test statistics $-\ln Q$ has a symmetric Gaussian probability density function.

\(^{19}\)Assuming a simple counting experiment with a true number of 100 background and 30 signal events, the one-sided probability $\text{CL}_{s+b}$ to fluctuate to equal or less than 111 observed event is 0.05. The corresponding value $\text{CL}_b = 0.05$ (which does not represent a probability) is however already reached between 105 and 106 events.
Group (TEVNPH) made the same information available for ten discrete data points in the mass range $155 \text{ GeV} \leq M_H \leq 200 \text{ GeV}$ based on preliminary searches using data samples of up to $3 \text{ fb}^{-1}$ integrated luminosity [69]. For the mass range $110 \text{ GeV} \leq M_H \leq 200 \text{ GeV}$, Tevatron results based on $2.4 \text{ fb}^{-1}$ are provided for $-2 \ln Q$, however not for the corresponding confidence levels [68].

To include the direct Higgs searches in the complete SM fit we interpret the $-2 \ln Q$ results for a given Higgs mass as measurements and derive a log-likelihood estimator quantifying the deviation of the data from the corresponding SM Higgs expectation. For this purpose we transform the one-sided $\text{CL}_{s+b}$ into two-sided confidence levels. The contribution to the $\chi^2$ estimator of the fit is thus obtained via

$$
\delta \chi^2 = 2 \cdot \left[ \text{Erf}^{-1}(1 - 2\text{CL}_{s+b}) \right]^2,
$$

where $\text{Erf}^{-1}$ is the inverse error function, and where the underlying probability density function has been assumed to be symmetric (cf. Footnote 18 on page 20).

Where available, we employ the $\text{CL}_{s+b}$ values determined with toy MC simulation by the experiments. For the Tevatron results in the mass range $110 \text{ GeV} \leq M_H \leq 150 \text{ GeV}$, where this information is not provided, we estimate $\text{CL}_{s+b}$ from the $-2 \ln Q$ values as measured in the data and expected for the $s + b$ hypothesis and the errors derived by the experiments for the $b$ hypothesis. We tested this approximation in the mass regions where $\text{CL}_{s+b}$ has been given and found a systematic overestimation of the contribution to our $\chi^2$ test statistics of about 30%, with small dependence on the Higgs mass. We thus rescale the test statistics in the mass region where the $\text{CL}_{s+b}$ approximation is used by the fudge factor 0.77.

Our method follows the spirit of a global SM fit and takes advantage from downward fluctuations of the background in the sensitive region to obtain a more restrictive limit on the SM Higgs production as is obtained with the modified frequentist approach. The resulting $\chi^2$ curves versus $M_H$ are shown in Fig. 1. The low-mass exclusion is obtained by the LEP searches, while the information above 120 GeV is contributed by the Tevatron experiments. Following the original figure, the Tevatron measurements have been interpolated by straight lines for the purpose of presentation and in the fit which deals with continuous $M_H$ values.

Constraints on the weak mixing angle can also be derived from atomic parity violation measurements in caesium, thallium, lead and bismuth. For heavy atoms one determines the weak charge,

$$
Q_W \approx Z (1 - 4 \sin^2 \theta_W) - N.
$$

Because the present experimental accuracy of 0.6% (3.2%) for $Q_W$ from Cs [73, 74] (Tl [75, 76]) is still an order of magnitude away from a competitive constraint on $\sin^2 \theta_W$, we do not include it into the fit. (Including it would reduce the error on the fitted Higgs mass by 0.2 GeV). Due to the same reason we do not include the parity violation left-right asymmetry measurement using fixed target polarised Möller scattering at low

---

20 Because experiments search for any (not necessarily SM) Higgs-like enhancement in the data, only the tail towards larger $-\ln Q$ values of the probability density function (corresponding to too few observed events with respect to the $s + b$ hypothesis) is integrated to compute $\text{CL}_{s+b}$, which is later used to derive $\text{CL}$ in the modified frequentist approach. In the global SM fit, however, one is interested in the compatibility between the SM hypothesis and the experimental data as a whole, and must hence account for any deviation (including too many Higgs candidates).

21 The use of $\text{Erf}^{-1}$ provides a consistent error interpretation when (re)translating the $\chi^2$ estimator into a confidence level via $\text{CL} = 1 - \text{Prob}(\chi^2, 1) = \text{Erf}(\sqrt{\chi^2/2})$.

22 The estimated $\text{CL}_{s+b}$ values will be replaced by the experimental values once provided by the TEVNPH Working Group.
4.2 Global Standard Model Analysis

Figure 1: The $\chi^2$ estimator versus $M_H$ derived from the experimental information on direct Higgs boson searches made available by the LEP Higgs Boson and the Tevatron New Phenomena and Higgs Boson Working Groups [67–69]. The solid dots indicate the Tevatron measurements. Following the original figure they have been interpolated by straight lines for the purpose of presentation and in the fit. See text for a description of the method applied.

$Q^2 = 0.026 \text{ GeV}^2 [77]$.\(^{23}\)

The NuTeV Collaboration measured ratios of neutral and charged current cross sections in neutrino-nucleon scattering at an average $Q^2 \simeq 20 \text{ GeV}^2$ using both muon neutrino and muon anti-neutrino beams [78]. The results derived for the effective weak couplings are not included in this analysis because of unclear theoretical uncertainties from QCD effects such as next-to-leading order corrections and nuclear effects of the bound nucleon parton distribution functions [79] (for reviews see, e.g., Refs. [80, 81]).

Although a large number of precision results for $\alpha_s$ at various scales are available, including recent 3NLO determinations at the $\tau$-mass scale [14, 15, 82, 83], we do not include these in the fit, because – owing to the weak correlation between $\alpha_s(M_Z^2)$ and $M_H$ (cf. Table 3) – the gain in precision on the latter quantity is insignificant.\(^{24}\) Leaving $\alpha_s(M_Z^2)$ free provides thus an independent and theoretically robust determination of the strong coupling at the $Z$-mass scale.

The anomaly of the magnetic moment of the muon $(g-2)_\mu$ has been measured very accurately to a relative precision of $5 \cdot 10^{-7}$. Because of the small muon mass the interesting weak corrections only set in at a similar size, and this observable is thus not included in the analysis. However, the sensitivity of $(g-2)_\mu$ to physics beyond the SM (expected to couple to the lepton mass-squared) is similar to that of the other observables.

\(^{23}\)The main success of this measurement is to have established the running of the weak coupling strength at the 6.4$\sigma$ level.

\(^{24}\)Including the constraint $\alpha_s(M_Z^2) = 0.1212 \pm 0.0011$ [15] into the fit moves the central value of $M_H$ by $+0.6$ MeV, and provides no reduction in the error.
4.2.3 Fit Results

All fits discussed in this section minimise the test statistics $\chi^2(y_{\text{mod}})$ defined in Eq. (1). The $\chi^2$ function accounts for the deviations between the observables given in Table 1 and their SM predictions (including correlations). Throughout this section we will discuss the results of two fits:

- The standard (“blue-band”) fit, which includes all the observables listed in Table 1, except for results from the direct Higgs searches.
- The complete fit includes also the results from the direct searches for the Higgs boson at LEP and the Tevatron using the method described in Section 4.2.2.

The standard (complete) fit converges at the global minimum value $\chi^2_{\text{min}} = 16.4$ ($\chi^2_{\text{min}} = 18.0$) for 13 (14) degrees of freedom, giving the naive p-value $\text{Prob}(\chi^2_{\text{min}}, 13) = 0.23$ ($\text{Prob}(\chi^2_{\text{min}}, 14) = 0.21$). See Section 4.2.5 for a more accurate toy-MC-based determination of the p-value. The results for the parameters and observables of the two fits are given in columns four and five of Table 1 together with their one standard deviation ($\sigma$) intervals derived from the $\Delta\chi^2$ estimator using a Gaussian approximation.

We discuss in the following some of the outstanding findings and features of the fit.

**Direct and indirect determination of observables, pulls**

To test the sensitivity of the SM fit to the various input observables, we consecutively disabled each of the observables in the fit and performed a log-likelihood scan of the disabled observable. Comparing the errors obtained in these indirect determinations with the available measurements reveals their importance for the fit. For example, the measurement of $M_Z$ is a crucial ingredient, albeit the available accuracy is not required. The indirect and direct determinations of $M_W$ are of similar precision, such that an improved measurement would immediately impact the fit. The same is true for the asymmetry $A_\ell$. On the other hand, due to an insufficient precision the heavy quark asymmetries $A_c$ and $A_b$ do not significantly impact the fit (the fit outperforms the measurements by almost two orders of magnitude in precision).

For further illustration, the pull values obtained from the difference between the fit result and the measurement divided by the total experimental error (not including the fit error) are shown for the complete fit in the left hand plot of Fig. 2 (the standard fit pulls are very similar). They reflect the known tension between the leptonic and hadronic asymmetries, though it is noticeable that no single pull value exceeds 3$\sigma$. The pulls of the $c$ and $b$ quark masses are very small indicating that variations of these masses within their respective error estimates has negligible impact on the fit. The same observation applies to $M_Z$ and $\Delta\alpha_{\text{had}}^{(5)}(M_Z^2)$ (and to a lesser extent even to $m_t$). Thus, without significant impact on the goodness-of-fit fit these parameters could have been fixed.

---

25 We have verified the Gaussian properties of the fit by sampling toy MC experiments. The results are discussed further down in this Section. In the following, unless otherwise stated, confidence levels and error ranges are derived using the Gaussian approximation $\text{Prob}(\Delta\chi^2, n_{\text{dof}})$.

26 Fixing $m_c$, $m_b$, $m_t$, $M_Z$ and $\Delta\alpha_{\text{had}}^{(5)}(M_Z^2)$ in the fit leads to only an insignificant increase of 0.03 in the overall $\chi^2_{\text{min}}$, reflecting the little sensitivity of the fit to these parameters varying within the ranges of their (comparably small) measurement errors. Of course, this does not prevent $M_H$ to strongly depend on the $m_t$ and $\Delta\alpha_{\text{had}}^{(5)}(M_Z^2)$ input values.
4.2 Global Standard Model Analysis

Figure 2: Comparing fit results with direct measurements: pull values for the complete fit (left), and results for $M_H$ from the standard fit excluding the respective measurements from the fit (right).

Figure 3: Determination of $M_H$ excluding all the sensitive observables from the standard fit, except for the one given. The results shown are not independent. The information in this figure is complementary to the one in the right hand plot of Fig. 2.
Correlations

The correlation coefficients between the fit parameters of the standard fit are given in Table 3. Significant are the correlations of \( -0.40 \) (+0.31) between \( \ln M_H \) and \( \Delta \alpha^{(5)}_{\text{had}}(M_Z^2) \) \( (m_t) \). An excellent precision of these two latter quantities is hence of primary importance for the Higgs-mass constraint. The correlation between \( \Delta \alpha^{(5)}_{\text{had}}(M_Z^2) \) and \( \alpha_S(M_Z^2) \) is due to the dependence of the hadronic vacuum polarisation contribution on the strong coupling that is known to the fit (cf. comment in Footnote 16 on page 18). The correlation coefficients obtained with the complete fit are very similar.

Prediction of the Higgs Mass

The primary target of the fits is the prediction of the Higgs mass. Some important aspects are discussed in this paragraph, while more detailed studies of the statistical properties of the prediction are presented in Section 4.2.4. The complete fit represents the most accurate estimation of \( M_H \) considering all available data. We find

\[
M_H = 116.4^{+18.3}_{-13.3} \text{ GeV}
\]  

(34)

where the error accounts for both experimental and theoretical uncertainties. The theory parameters \( \delta_{\text{th}} \) lead to an uncertainty of 8 GeV on \( M_H \), which does however not yet significantly impact the error in (34) because of the spread among the input measurements that are sensitive to \( M_H \) (cf. Fig. 3).27 As seen in Fig. 12 of Section 4.3, once the measurements are (made) compatible, the theoretical errors become visible by the uniform plateau around the \( \Delta \chi^2 \) minimum, and also fully contribute to the fit error. The 2\( \sigma \) and 3\( \sigma \) allowed regions of \( M_H \), including all

\[27\] This is a subtle feature of the fit treatment that we shall illustrate by mean of a simple example. Consider two identical uncorrelated measurements of an observable \( A \): \( 1 \pm 1 \pm 1 \) and \( 1 \pm 1 \pm 1 \), where the first errors are statistical and the second theoretical. The weighted average of these measurements gives \( \langle A \rangle = 1 \pm 0.7 \pm 1 = 1 \pm 1.7 \), where for the last term statistical and theoretical errors (likelihoods) have been combined. If the two measurements only barely overlap within their theoretical errors, e.g., \( 1 \pm 1 \pm 1 \) and \( 3 \pm 1 \pm 1 \), their weighted average gives \( \langle A \rangle = 2 \pm 1 \). Finally, if the two measurements are incompatible, e.g., \( 1 \pm 1 \pm 1 \) and \( 5 \pm 1 \pm 1 \), one finds \( \langle A \rangle = 3 \pm 0.7 \), i.e., the theoretical errors are only used to increase the global likelihood value of the average, without impacting the error. This latter situation occurs in the \( M_H \) fits discussed here (although the theoretical errors in these fits are attached to the theory predictions rather than to the measurements, which however does not alter the conclusion).
errors, are [114, 145] GeV and [[113, 168] and [180, 225]] GeV, respectively. The result for the standard fit without the direct Higgs searches is
\[ M_H = 80^{+30}_{-23} \text{ GeV} \] (35)
and the 2σ and 3σ intervals are respectively [39, 155] GeV and [26, 209] GeV. The 3σ upper limit is tighter than for the complete fit because of the increase of the best fit value of \( M_H \) in the complete fit. The contributions from the various measurements to the central value and error of \( M_H \) in the standard fit are given in the right hand plot of Fig. 2, where all input measurements except for the ones listed in a given line are used in the fit. It can be seen that, e.g., the measurements of \( m_t \) and \( M_W \) are essential for an accurate estimation of the \( M_H \). The complementary information where all measurements directly sensitive to \( M_H \) are excluded from the fit, except for the one listed, is given in Fig. 3.\(^{28}\)

The compatibility among the measurements exhibiting the best sensitivity to \( M_H \) (cf. Fig. 3) can be estimated by (for example) repeating the global fit where the least compatible of the measurements (here \( A_{FB}^{0, b} \)) is removed, and by comparing the \( \chi^2_{\text{min}} \) estimator obtained in that fit to the one of the full fit (here the standard fit). To assign a probability to the observation, the \( \Delta \chi^2_{\text{min}} \) obtained this way must be gauged with toy MC experiments to take into account the “look-elsewhere” effect introduced by the explicit selection of the pull outlier. We find that in (1.4±0.1)% (“2.5σ”) of the toy experiments, the \( \Delta \chi^2_{\text{min}} \) found exceeds the \( \Delta \chi^2_{\text{min}} = 8.0 \) observed in current data.

In spite of the significant anticorrelation between \( M_H \) and \( \Delta \alpha_{\text{had}}^{(5)}(M_Z^2) \), the present uncertainty in the latter quantity does not strongly impact the precision obtained for \( M_H \). Using the theory-driven, more precise phenomenological value \( \Delta \alpha_{\text{had}}^{(5)}(M_Z^2) = (277.0 \pm 1.6) \cdot 10^{-4} \) [84], we find for the standard fit \( M_H = 80^{+28}_{-22} \text{ GeV} \).

**Prediction of the top mass**

Figure 4 shows the \( \Delta \chi^2 = \chi^2 - \chi_{\text{min}}^2 \) profile as a function of \( m_t \) obtained for the complete fit (solid line) and the standard fit (dashed line) both excluding the measurement of the top-quark mass. The one two and three standard deviations from the minimum are indicated by the crossings with the corresponding horizontal lines. We find from the complete fit
\[ m_t = 178.2^{+9.8}_{-4.2} \text{ GeV} \] (36)
which, albeit less precise, agrees with the experimental number (cf. Table 1) indicated in Fig. 4 with its 1σ uncertainty. The result for the standard fit without direct \( m_t \) measurement is \( m_t = 177.0^{+10.8}_{-8.0} \) GeV. The insertion of the direct (LEP) Higgs searches leads to a more restrictive constraint in particular at lower top-quark masses.

\(^{28}\)The uncertainty in the \( f_{\text{had}} \) parameters that are correlated to \( M_H \) (mainly \( \Delta \alpha_{\text{had}}^{(5)}(M_Z^2) \) and \( m_t \)) contributes to the errors shown in Fig. 3, and generates a correlation between the four \( M_H \) values found. This must be taken into account when deriving p-values to quantify their mutual compatibility.
4.2 Global Standard Model Analysis

Figure 4: $\Delta \chi^2$ as a function of $m_t$ for the complete fit (solid) and the standard fit (dotted) both excluding the direct $m_t$ measurement which is indicated with the respective 1$\sigma$ error bar.

The strong and electromagnetic couplings

As detailed in Section 4.2.2 we do not include direct measurements of the strong coupling in the fit. From the complete fit we find for the strong coupling at the $Z$-mass scale

$$\alpha_s(M^2_Z) = 0.1193 \pm 0.0028 \pm 0.0001$$ \hspace{1cm} (37)

where the first error is experimental (including also the propagated uncertainties from the errors in the $c$ and $b$ quark masses) and the second due to the truncation of the perturbative QCD series. It includes variations of the renormalisation scale between $0.6 M_Z < \mu < 1.3 M_Z$ \cite{15}, of massless terms of order $\alpha_s^0(M_Z)$ and higher, and of quadratic massive terms of order and beyond $\alpha_s^4(M_Z)$ (cf. Appendix A.4).\textsuperscript{29} Equation (37) represents the theoretically most robust determination of $\alpha_s$ to date. It is in excellent agreement with the recent 3NLO result from $\tau$ decays \cite{14, 15}, $\alpha_s(M^2_Z) = 0.1212 \pm 0.0005 \pm 0.0008 \pm 0.0005$, where the errors are experimental (first) and theoretical (second and third), the latter error being further subdivided into contributions from the prediction of the $\tau$ hadronic width (and spectral moments), and from the evolution to the $Z$-mass scale.\textsuperscript{30} Because of their precision, and the almost two orders of magnitude scale difference, the $\tau$ and $Z$-scale measurements of $\alpha_s$ represent the best current test of the asymptotic freedom property of QCD.

Finally, the fit result for $\Delta \alpha^{(5)}_{\text{had}}(M^2_Z)$ without using the constraint from the phenomenological analysis in the fit (but including the constraint from the direct Higgs searches, cf. Table 1)

\textsuperscript{29}The uncertainty related to the ambiguity between the use of fixed-order perturbation theory and the so-called contour-improved perturbation theory to solve the contour integration of the complex Adler function has been found to be very small ($3 \cdot 10^{-5}$) at the $Z$-mass scale \cite{15}.

\textsuperscript{30}Another analysis exploiting the $\tau$ hadronic width and its spectral functions, but using a different set of spectral moments than \cite{15}, finds $\alpha_s(M^2_Z) = 0.1187 \pm 0.0016$ \cite{83}. An analysis of the $\tau$ hadronic width relying on fixed-order perturbation theory finds $\alpha_s(M^2_Z) = 0.1180 \pm 0.0008$, where all errors have been added in quadrature \cite{82}.
precisely establishes a running QED coupling, and can be translated into the determination \(\alpha^{-1}(M_Z)_{\text{fit}} = 128.99 \pm 0.08\). The result is in agreement with the phenomenological value \(\alpha^{-1}(M_Z)_{\text{ph}} = 128.937 \pm 0.030\) [62].

### 4.2.4 Properties of the Higgs-Mass Constraint

We proceed with studying the statistical properties of the constraints (34) and (35). Figure 5 (top) shows the \(\Delta \chi^2\) profile versus \(M_H\) obtained for the standard fit (outermost envelope). Also shown is the 95% CL exclusion region obtained from the direct searches at LEP [67]. It exceeds the best fit value of the standard fit. The \(\hat{R}\) fit approach provides an inclusive treatment of all types of theoretical uncertainties considered in the fit. Fixing the \(\delta_{\text{th}}\) parameters at zero in the fit (which is equivalent to ignoring the corresponding theoretical uncertainties) results in a narrower log-likelihood curve, with a +0.6 larger global \(\chi^2_{\text{min}}\) value, and a shift in \(M_H\) at this minimum of +2.4 GeV with respect to the result of the standard fit. The difference between the two envelopes obtained with freely varying and fixed \(\delta_{\text{th}}\) parameters is highlighted by the shaded band in Fig. 5 (top).

In previous electroweak fits [89] theoretical uncertainties were accounted for by independently shifting the SM prediction of each affected observable by the size of the estimated theoretical uncertainty, and taking the maximum observed cumulative deviation in \(M_H\) as theoretical error. The error envelope obtained this way is shown in Fig. 7. The dotted curve in the middle of the shaded band is the result of a fit ignoring all theoretical uncertainties. The shaded band illustrates the maximum deviations of the \(\Delta \chi^2\) curves obtained with shifted predictions. Including the systematic uncertainties in this way yields a 1\(\sigma\) interval of [55, 122] GeV and 95% (99%) CL upper limits of 162 GeV (192 GeV) respectively. For comparison the solid curve in Fig. 7 shows the result of the standard fit using the \(\hat{R}\) fit scheme. [32] More detailed studies of systematic theoretical uncertainties are reported in [55].

The \(\Delta \chi^2\) curve versus \(M_H\) for the complete fit is shown in Fig. 5 (bottom). Again the shaded band indicates the difference between the two envelopes obtained with freely varying and fixed \(\delta_{\text{th}}\) parameters, both normalised to the same \(\chi^2_{\text{min}}\) (from the fit with free \(\delta_{\text{th}}\) parameters). The inclusion of the direct Higgs search results from LEP leads to a strong rise of the \(\Delta \chi^2\) curve below \(M_H = 115\) GeV. The data points from the direct Higgs searches at the Tevatron, available in the range \(110\) GeV \(< M_H < 200\) GeV with linear interpolation between the points, increases the \(\Delta \chi^2\) estimator for Higgs masses above 140 GeV beyond that obtained from the standard fit.

We have studied the Gaussian (parabolic) properties of the \(\Delta \chi^2\) estimator to test whether the interpretation of the profile likelihood in terms of confidence levels can be simplified. Figure 6 gives the 1–CL derived for \(\Delta \chi^2\) as a function of the \(M_H\) hypothesis for various scenarios: Gaussian approximation \(\text{Prob}(\Delta \chi^2, 1)\) of the standard fit including theory errors (dashed/red line), Gaussian approximation of the standard fit ignoring theory errors, i.e., fixing all \(\delta_{\text{th}}\) parameters at zero (solid/black line), and an accurate evaluation using toy MC experiments ignoring theory errors (shaded/green area). Also shown is the complete fit result with Gaussian approximation.

---

[31] This result is complementary (though more precise) to the LEP measurements of the scale dependence of \(\alpha\) using, e.g., small and large-angle Bhabha scattering at low energy [85, 86] and high energies [87], respectively, or cross section and asymmetry measurements at high energies [88].

[32] The inclusion of the theory errors via freely varying parameters (\(\hat{R}\) fit) leads to a decrease in the global \(\chi^2_{\text{min}}\) of the fit. Incompatibilities in the input observables (which may be due to statistical fluctuations) thus attenuate the numerical effect of the theoretical errors on the fitted parameter (here \(M_H\)). See footnote 27 on page 25 for an illustration of this effect.
Figure 5: $\Delta \chi^2$ as a function of $M_H$ for the standard fit (top) and the complete fit (bottom). The solid (dashed) lines give the results when including (ignoring) theoretical errors. The minimum $\chi^2_{\text{min}}$ of the fit including theoretical errors is used for both curves in each plot to obtain the offset-corrected $\Delta \chi^2$. 
4.2 Global Standard Model Analysis

Figure 6: The $1 - \text{CL}$ function derived from the $\Delta\chi^2$ estimator versus the $M_H$ hypothesis (cf. Fig. 5 (top) for $\Delta\chi^2$ versus $M_H$) for the standard fit. Compared are the Gaussian approximation $\text{Prob}(\Delta\chi^2, 1)$ for the standard fit with (dashed/red line) and without theoretical errors (solid/black line), respectively, to an evaluation based on toy MC simulation for which theoretical errors have been ignored. Also given is the result using $\text{Prob}(\cdot)$ for the complete fit (dotted/blue line).

The toy experiments are sampled using as underlying model the best fit parameters (and corresponding observables) obtained for each $M_H$ hypothesis. As described in Section 2.4, such a hypothesis is incomplete from a frequentist point of view because the true values of the nuisance parameters are unknown. However, the persuasively Gaussian character of the fit makes us confident that our assumption is justified in the present case (cf. the additional discussion and tests in Section 4.2.5). The correlations given in Table 2 are taken into account for the generation of the toy experiments. Theoretical errors being of non-statistical origin have been excluded from this test, which aims at gauging the statistical properties of the test statistics. The curves in Fig. 6 show agreement between the Gaussian approximation without theoretical errors, and the toy MC result. It proves that the fit is well behaved, and the $\Delta\chi^2$ estimator can be interpreted as a true $\chi^2$ function.

Figure 8 shows the 68%, 95% and 99% CL contours for the variable pairs $m_t$ vs. $M_H$ (top) and $\Delta\alpha^{(5)}(M_Z^2)$ vs. $M_H$ (bottom), exhibiting the largest correlations in the fits. The contours are derived from the $\Delta\chi^2$ values found in the profile scans using $\text{Prob}(\Delta\chi^2, 2)$ (cf. discussion in Section 2.3). Three sets of fits are shown in these plots: the largest/blu (narrower/purple)

---

33 Examples from other particle physics areas, such as the determination of the CKM phase $\gamma$ via direct CP violation measurements in $B$ decays involving charm, show that this approximation can lead to severe undercoverage of the result [21]. As described in Section 2, the full treatment would require a numerical minimisation of the exclusion $\text{CL}$ with respect to any true SM (nuisance) parameter set used to generate the toy MC samples (cf. Refs. [21, 22]). More formally, this corresponds to solving $\text{CL}(M_H) = \min_\mu \text{CL}_\mu(M_H)$, where $\mu$ are the nuisance parameters of the fit and $\text{CL}_\mu(M_H) = \int_{\Delta\chi^2}^{\infty} F(\Delta\chi^2|M_H, \mu)d\Delta\chi^2$, and where $F(\Delta\chi^2|M_H, \mu)$ is the probability density function of $\Delta\chi^2$ for true $M_H$ and $\mu$ determined from toy MC simulation.
4.2 Global Standard Model Analysis

Figure 7: $\Delta \chi^2$ as a function of $M_H$ with an alternative treatment of theory uncertainties [89]. Shown are the results of a standard fit ignoring theoretical uncertainties (dotted line), the regions determined from the maximum deviation in $\Delta \chi^2$ achieved by shifting the SM predictions of all observables according to 1 “standard deviation” of the various theory uncertainties (shaded band) and for comparison the result of the standard fit (solid curve) in which theoretical uncertainties are included in the $\chi^2$ calculation.

allowed regions are derived from the standard fit excluding (including) the measured values (indicated by shaded/light green horizontal bands) for respectively $m_t$ and $\Delta \alpha^{(5)}_\text{had}(M_Z^2)$ in the fits. The correlations seen in these plots are approximately linear for $\ln M_H$ (cf. Table 3). The third set of fits, providing the narrowest constraints, uses the complete fit, i.e., including in addition to all available measurements the direct Higgs searches. The structure of allowed areas reflects the presence of local minima in the bottom plot of Fig. 5. Figure 9 compares the direct measurements of $M_W$ and $m_t$, shown by the shaded/green 1$\sigma$ bands, with the 68%, 95% and 99% CL constraints obtained with again three fit scenarios. The largest/blue (narrowest/green) allowed regions are again the result of the standard fit (complete fit) excluding (including) the measured values of $M_W$ and $m_t$. The results of the complete fit excluding the measured values are illustrated by the narrower/yellow allowed region. Good agreement is observed between indirect determination (narrower/yellow) and direct measurements (shaded/green bands).

4.2.5 Probing the Standard Model

We evaluate the p-value of the global SM fit following the prescription outlined in Section 2.4. A toy MC sample with 10 000 experiments has been generated using as true values for the SM parameters the outcomes of the global fit (see the remarks below and in Section 2.4 and Footnote 33 on page 30 about the limitation of this method). For each toy simulation, the central values of all the observables used in the fit are generated according to Gaussian distributions around their expected SM values (given the parameter settings) with standard deviations equal
Figure 8: Contours of 68%, 95% and 99% CL obtained from scans of fits with fixed variable pairs $m_t$ vs. $M_H$ (top) and $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$ vs. $M_H$ (bottom). The largest/blue (narrower/purple) allowed regions are the results of the standard fit excluding (including) the measurements of $m_t$ (top) and $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$ (bottom). The narrowest/green areas indicate the constraints obtained for the complete fit including all the available data. The horizontal bands indicate the 1$\sigma$ regions of respectively the $m_t$ measurement and $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$ phenomenological determination.
to the full experimental errors taking into account all correlations. It is assumed that central values and errors are independent. The *R*fit treatment of theoretical uncertainties allows the fit to adjust theoretical predictions and parameters at will within the given error ranges, and – as opposed to measurements – the theoretical parameters cannot be described by a probability density distribution and are thus not fluctuated in the toy MC. For each toy MC sample, the *complete fit* is performed (i.e., including the results from the direct Higgs searches) yielding the $\chi^2_{\text{min}}$ distribution shown by the light shaded histogram in Fig. 10. The distribution obtained when fixing the $\delta_{\text{th}}$ parameters at zero is shown by the dark shaded/green histogram. Including the theoretical uncertainties reduces the number of degrees of freedom in the data and hence shifts the distribution to lower values. Overlaid is the $\chi^2$ function expected for Gaussian observables and 14 degrees of freedom. Fair agreement with the empirical toy MC distribution for fixed $\delta_{\text{th}}$ is observed.

The monotonously decreasing curves in Fig. 10 give the p-value of the SM fit as a function of $\chi^2_{\text{min}}$, obtained by integrating the sampled normalised $\chi^2$ function between $\chi^2_{\text{min}}$ and infinity. The value of the global SM fit is indicated by the arrow. Including theoretical errors in the fit gives

$$p\text{-value (data|SM)} = 0.22 \pm 0.01 \pm 0.02,$$

(38)

where the first error is statistical, determined by the number of toy experiments performed, and the second accounts for the shift resulting from fixed $\delta_{\text{th}}$ parameters. The probability of falsely rejecting the SM, expressed by the result (38), is sufficient and no significant requirement for

\[\text{modified text}\]
Figure 10: Result of the MC toy analysis of the complete fit. Shown are the $\chi^2_{\text{min}}$ distribution of a toy MC simulation (open histogram), the corresponding distribution for a complete fit with fixed $\delta_{\text{th}}$ parameters at zero (shaded/green histogram), an ideal $\chi^2$ distribution assuming a Gaussian case with $n_{\text{dof}} = 14$ (black line) and the p-value as a function of the $\chi^2_{\text{min}}$ of the global fit.

physics beyond the SM can be inferred from the fit.

To validate the $p_{\text{best fit}} \approx \min_{\mu} p_{\mu}$ assumption used in the above study, we have generated several true parameter sets ($\mu$) in the vicinity of the best fit result (varying parameters incoherently by $\pm 1\sigma$ around their measurement errors), and repeated the toy-MC based p-value evaluation for each of them. The $\chi^2$ probability density distributions derived from these tests have been found to be compatible with each other, leading to similar p-values in all cases studied. It supports the robustness of the result (38).

We have extended the above analysis by deriving p-values for the standard fit as a function of the true Higgs mass. The results are shown in Fig. 11. For values of $M_H$ around 80 GeV, corresponding to the $\chi^2_{\text{min}}$ of the standard fit, p-values of about 0.25 are found. With higher $M_H$ the p-value drops reaching the $2\sigma$ level at $M_H = 190$ GeV and the $3\sigma$ level at $M_H = 270$ GeV.

4.3 Prospects for the LHC and ILC

The next generation of particle colliders, namely LHC and ILC, have the potential to significantly increase the precision of most electroweak observables that are relevant to the fit. This will improve the predictive power of the fit, and – in case of a Higgs discovery – its sensitivity to physics beyond the SM by directly confronting theory and experiment, and by testing the overall goodness-of-fit of the SM.

At the LHC the masses of the $W$ boson and the top quark are expected to be measured with

---

35 By fixing $M_H$ the number of degrees of freedom of the fit is reduced compared to the standard fit resulting in a larger average $\chi^2_{\text{min}}$ and thus in a larger p-value.
Figure 11: P-value of the electroweak fit versus $M_H$ as obtained from toy MC simulation. The error band represents the statistical error from the MC sampling.

precisions reaching $\sigma(M_W) = 15$ MeV and $\sigma(m_t) = 1.0$ GeV [16, 17, 90, 91], respectively. At the ILC it is expected that the top mass can be measured to an experimental precision of approximately $\sigma(m_t) = 50$ MeV using a threshold scan and an adapted mass definition [18, 94]. This should translates into an error of 100–200 MeV on the $\overline{\text{MS}}$-mass depending on the accuracy of the strong coupling constant [18, 94, 95]. More improvements are expected for a linear collider running with high luminosity and polarised beams at the $Z$ resonance (GigaZ). The $W$-mass can be measured to 6 MeV from a scan of the $WW$ threshold [18]. The effective weak mixing angle for leptons can be measured to a precision of $1.3 \cdot 10^{-5}$ from the left-right asymmetry, $A_{LR}$ [18, 96]. At the same time, the ratio of the $Z$ leptonic to hadronic partial decay widths, $R_0^\ell$, can be obtained to an absolute experimental precision of 0.004 [97]. These numbers do not include theoretical uncertainties since it is assumed that substantial theoretical progress will be realised in the years left before these measurements are possible.

At the time when the new measurements from the LHC experiments, and later the ILC, become available, an improved determination of $\Delta\alpha^{(5)}_{\text{had}}(M_Z^2)$ will be needed to fully exploit the new precision data. This in turn requires a significant improvement in the quality of the hadronic cross section data at energies around the $c\bar{c}$ resonances and below, and a better knowledge of the $c$ and $b$ quark masses entering the perturbative prediction of the cross sections where applicable, which serve as input to the dispersion integral. Reference [98] quotes expected uncertainties of

\footnote{CMS expects a systematic (statistical) precision of better than 20 MeV (10 MeV) for an integrated luminosity of 10 fb$^{-1}$ [17, 92]. It uses a method based on solely the reconstruction of the charged lepton transverse momentum, which has reduced systematic uncertainties compared to reconstructing the transverse $W$ mass, with the downside of a smaller statistical yield. In an earlier study using the transverse-mass method, ATLAS finds a systematic (statistical) uncertainty of better than 25 MeV (2 MeV), for the same integrated luminosity [16]. Combining both, lepton channels and experiments, a final uncertainty of about 15 MeV is anticipated in [90], which is used here. A recent study finds that uncertainties of $\sigma(M_W) \sim 7$ MeV might be achievable for each lepton channel (with similar uncertainties for both aforementioned experimental approaches), by heavily relying on the calibration of the lepton momenta and reconstruction efficiencies at the $Z$ pole [93].}
4.3 Prospects for the LHC and ILC

The dominant theoretical uncertainties affecting the electroweak fit arise from the missing higher order corrections in the predictions of $M_W$. The estimated improvement for $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$ (given in parenthesis of the corresponding line) over the current uncertainty is unrelated to these accelerators, and must come from new low-energy hadronic cross section measurements and a more accurate theory (see text). The lower rows give the results obtained for $M_H$ and $\alpha_s(M_Z^2)$. For $M_H$ are also given the results with improved $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$ precision (parentheses – this has no impact on $\alpha_s(M_Z^2)$), and when in addition ignoring the theoretical uncertainties [brackets]. Note that all errors obtained on $M_H$ are strongly central value dependent (see text).

$$\sigma(\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)) \sim 7 \cdot 10^{-5} \text{ and } 5 \cdot 10^{-5}, \text{ compared to presently } 22 \cdot 10^{-5}, \text{ if the relative precision on the cross sections attains } 1\% \text{ below the } J/\psi \text{ and the } \Upsilon \text{ resonances, respectively.}$$

The dominant theoretical uncertainties affecting the electroweak fit arise from the missing higher order corrections in the predictions of $M_W$ and $\sin^2\theta_W^\text{eff}$ (cf. Section 4.1.4), which contribute similarly to the error on $M_H$. They amount to 10 GeV (13 GeV) at $M_H = 120$ GeV (150 GeV). Significant theoretical effort is needed to reduce these.

A summary of the current and anticipated future uncertainties on the quantities $M_W$, $m_t$, $\sin^2\theta_W^\text{eff}$, $R^0$, and $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$, for the LHC, ILC, and the ILC with GigaZ option, is given in Table 4. By using these improved measurements the global SM fit (not using the results from direct Higgs searches nor measurements of $\alpha_s(M_Z^2)$) results in the constraints on the Higgs mass and $\alpha_s(M_Z^2)$ quoted in Table 4. For all four scenarios the true Higgs mass has been assumed to be $M_H = 120$ GeV and the central values for all observables are adjusted such that they are consistent with this $M_H$ value. All fits are performed using respectively the present uncertainty on $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$, and assuming the above-mentioned improvement. For the latter case results for $M_H$ are given including (parentheses) and excluding [brackets] theory uncertainties. With the

Table 4: Measurement prospects at future accelerators for key observables used in the electroweak fit, and their impact on the electroweak fit. The columns give, from the left to the right: present errors, the expected uncertainties for the LHC with 10 fb$^{-1}$ integrated luminosity, the ILC without and with the option to run at the $Z$ resonance and along the $W$-pair production threshold (GigaZ) for one year of nominal running. The estimated improvement for $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$ (given in parenthesis of the corresponding line) over the current uncertainty is unrelated to these accelerators, and must come from new low-energy hadronic cross section measurements and a more accurate theory (see text). The lower rows give the results obtained for $M_H$ and $\alpha_s(M_Z^2)$. For $M_H$ are also given the results with improved $\Delta \alpha^{(5)}_{\text{had}}(M_Z^2)$ precision (parentheses – this has no impact on $\alpha_s(M_Z^2)$), and when in addition ignoring the theoretical uncertainties [brackets]. Note that all errors obtained on $M_H$ are strongly central value dependent (see text).
Figure 12: Constraints on $M_H$ obtained for the four scenarios given in Table 4, assuming the improvement $\sigma(\Delta \alpha_{\text{had}}^{(5)}(M_Z^2)) = 7 \cdot 10^{-5}$ for all prospective curves. Shown are, from wider to narrower $\chi^2$ curves: present constraint, LHC expectation, ILC expectations with and without GigaZ option. The $1\sigma$ errors for $M_H$ given in Table 4 correspond to the $\Delta \chi^2 = 1$ intervals obtained from these graphs. The shaded bands indicate the effect of theoretical uncertainties.

GigaZ option, the uncertainty from $\Delta \alpha_{\text{had}}^{(5)}(M_Z^2)$ would dominate the overall fit error on $M_H$ if no improvement occurred. We emphasise that due (by part) to the logarithmic dependence, the error obtained on $M_H$ is strongly $M_H$ dependent: with the same precision on the observables, but central values that are consistent with a true value of 150 GeV, one would find $M_H = 150^{+66}_{-49}$ GeV in average, i.e., an error increase over the $M_H = 120$ GeV case of almost 30%. With the GigaZ option and the resulting improvement for $R_\ell^0$, the uncertainty on $\alpha_s(M_Z^2)$ from the fit is reduced by a factor of four.

The $M_H$ scans obtained for the four scenarios, assuming the improved $\Delta \alpha_{\text{had}}^{(5)}(M_Z^2)$ precision to be applicable for all future (LHC and beyond) scenarios, are shown in Fig. 12. The shaded bands indicate the effect of the current theoretical uncertainties. As expected the theoretical errors included with the $R$fit scheme are visible by a broad plateau around the $\Delta \chi^2$ minimum.

A discovery of the Higgs boson at the LHC in the clean decay mode $H \rightarrow \gamma \gamma$ ($H \rightarrow 2\ell 2\ell'$) for a light (heavy) Higgs would soon allow a precision measurement of $M_H$ beyond the percent level. Inserting the measurement into the global electroweak fit would lead to a prediction of the $W$ boson mass with 13 MeV error, of which 5 MeV is theoretical. Prediction and measurement could be directly confronted. More inclusively, the $p$-value of the data given the SM could be determined as a direct test of the goodness of the SM fit.
5 Extending the SM Higgs Sector – The Two Higgs Doublet Model

Two Higgs Doublet Models (2HDM) [99] are simple extensions to the SM Higgs sector, only introducing an additional $SU(2)_L \times U(1)_Y$ Higgs doublet with hypercharge $Y = 1$, leading to five physical Higgs bosons. Three Higgs bosons ($A^0, h^0, H^0$) are electrically neutral and the two remaining ones ($H^\pm$) are electrically charged. The free parameters of the 2HDM are the Higgs boson masses $M_{A^0}, M_{h^0}, M_{H^0}$ and $M_{H^\pm}$, the ratio of the vacuum expectation values of the two Higgs doublets $\tan \beta = v_2/v_1$, occurring in the mixing of charged and neutral Higgs fields, and the angle $\alpha$, governing the mixing of the neutral CP-even Higgs fields.

Models with two Higgs doublets intrinsically fulfil the empirical equality $M_W^2 \approx M_Z^2 \cos^2 \theta_W$. They also increase the maximum allowed mass of the lightest neutral Higgs boson for electroweak Baryogenesis scenarios to values not yet excluded by LEP (see, e.g., [100]), and introduce CP violation in the Higgs sector. Flavour changing neutral currents can be suppressed with an appropriate choice of the Higgs-fermion couplings (see e.g., Ref. [101]). For example, in the Type-I 2HDM this is achieved by letting only one Higgs doublet couple to the fermion sector. In the Type-II 2HDM [102], which is chosen for this analysis, one Higgs doublet couples to the up-type quarks and leptons only, while the other one couples only to the down-type quarks and leptons. It resembles the Higgs sector in the Minimal Supersymmetric Standard Model.

Our analysis is restricted to observables that are sensitive to corrections from the exchange of a charged Higgs boson. From these we derive constraints on the allowed charged-Higgs mass $M_{H^\pm}$ and $\tan \beta$. Direct searches for the charged Higgs have been performed at LEP and the Tevatron. LEP has derived a lower limit of $M_{H^\pm} > 78.6$ GeV at 95% CL [103], for any value of $\tan \beta$.

5.1 Input Observables

The constraints on the charged Higgs are currently dominated by indirect measurements, as opposed to direct searches at high-energy accelerators. A multitude of heavy flavour observables mainly from $B$-meson decays is available whose sensitivity to the 2HDM parameters varies however substantially, either due to limited experimental precision in case of rare decays, or because specific 2HDM contributions are strongly suppressed. The most relevant observables for the search of Type-II 2HDM signals are the electroweak precision variable $R_0^b$, branching fractions of rare semileptonic $B, D$ and $K$ decays, and loop-induced radiative $B$ decays.\footnote{Decays of $\tau$ and $\mu$ leptons can also occur through charged-Higgs tree diagrams giving anomalous contributions to the decay parameters (Michel parameters [104]) measured in these decays. Their present sensitivity is however not competitive with the other observables (a 95% CL limit of $M_{H^\pm} > 1.9$ GeV $\cdot$ $\tan \beta$ is currently achieved from $\tau$ decays [105], see also [106] for a review of the $\mu$ decay parameters).}

A summary of the experimental input used for this analysis is given in Table 5.

5.1.1 Hadronic Branching Ratio of $Z$ to $b$ Quarks $R_0^b$

The sensitivity of $R_0^b$ to a charged Higgs boson arises from an exchange diagram modifying the $Zb\bar{b}$ coupling. The corresponding corrections of the SM prediction have been calculated in Ref. [107] and are given in Eqs. (6.3) and (6.4) thereof. The left- (right-) handed corrections to the effective couplings $\delta g_{(L,R)}^b$ are proportional to $\cot^2 \beta$ ($\tan^2 \beta$) and to $R/(R−1) − R \log R/(R−...
5.1 Input Observables

The leptonic decay rate of a pseudoscalar meson $\Gamma (P \to \ell \nu) = \frac{B(P \to \ell \nu)}{\tau_P} = \frac{G_F^2 f_P^2 m_P^2}{16\pi^3} \left( 1 - \frac{m_\ell^2}{m_P^2} \right) |V_{q_1q_2}|^2,$ \hspace{1cm} (39)

where $m_P$ ($m_\ell$) is the mass of the pseudoscalar meson (lepton), $|V_{q_1q_2}|$ is the magnitude of the CKM matrix element of the constituent quarks in $P$, and $f_P$ is the weak decay constant.

For $P = B$ (implying $B^\pm = B_{c\bar{c}}^\pm$) we use the world averages \cite{109} $\tau_{B^\pm} = (1.639 \pm 0.009)$ ps, and $|V_{ub}| = (3.81 \pm 0.47) \cdot 10^{-3}$, where we have performed an average of inclusive and exclusive measurements. For the $B$ decay constant we use the value $f_B = (216 \pm 22)$ MeV, obtained by the HPQCD Collaboration from unquenched Lattice QCD calculations \cite{112}. For meson and lepton masses we use the values of Ref. \cite{60}. It is possible to use for the r.h.s. of Eq. (39) additional constraints from the global CKM fit enhancing the information on $|V_{q_1q_2}|$ beyond that of the direct measurement through the fit of the Wolfenstein parameters $\overline{\lambda}$, $\overline{\xi}$, and on $f_B$ through
the measurement of the $B^0\bar{B}^0$ mixing frequency. This assumes that the measurements entering the fit are free from new physics contributions. It is certainly the case for the charged Higgs, but cannot be excluded for the CP-violation and neutral-$B$ mixing observables. Hence, albeit using the global CKM fit is an interesting test, it cannot replace the direct SM prediction of Eq. (39) based on tree-level quantities and lattice calculations only. Not using the direct measurements, the global CKM fit gives $|V_{ub}| = (3.44^{+0.22}_{-0.17}) \times 10^{-3}$, and for the complete prediction $\mathcal{B}(B \to \tau \nu) = 0.83^{+0.27}_{-0.10}$ [113]. This latter result is about 1.9$\sigma$ below the one from the “tree-level” determination, and a similar discrepancy is found for $B \to \mu \nu$ (cf. Table 5).

The charged-Higgs amplitude contributes to the leptonic decays modifying Eq. (39) by a scaling factor $r_H$. In the Type-II 2HDM the $b$ quark couples only to one of the Higgs doublets at tree level so that the scaling factor for the decays $B \to \tau \nu$ and $B \to \mu \nu$ reads [114]

$$r_H = \left(1 - m_B^2 \frac{\tan \beta}{M_{H^\pm}}\right)^2,$$

which can lead to both, an increase and a decrease in the branching fraction, depending on whether the $W^\pm$ and $H^\pm$ amplitudes interfere constructively or destructively.

The rare leptonic decay $B \to \tau \nu$ has been observed by the BABAR and Belle Collaborations [115–117], with an average branching fraction of $\mathcal{B}(B \to \tau \nu) = (1.51 \pm 0.33) \times 10^{-4}$ [117]. Only upper limits are available for the muon channel so far, the tightest one, $\mathcal{B}(B \to \mu \nu) < 1.3 \times 10^{-6}$ at 90% CL ($-12 \pm 20$ fitted events), being found by BABAR [118]. For lack of an experimental likelihood we use the measured branching fraction of $(5.7 \pm 7.1_{\text{stat}} \pm 6.8_{\text{syst}}) \times 10^{-7}$.

For $P = K$, contributions from a charged Higgs are suppressed by $(m_K/m_B)^2$ relative to leptonic $B$ decays. Moreover, due to the smaller phase space for hadronic final states, leptonic decays have large branching fractions, which – on the other hand – have been measured to an excellent 0.2% relative accuracy for $\ell = \mu$. We follow the approach of Ref. [119] and compare $|V_{us}|$ determined from helicity suppressed $K \to \mu \nu$ decays and helicity allowed $K \to \pi \mu \nu$ decays, considering the expression

$$R_{\ell 23} = \frac{|V_{us}(K \to \mu \nu)| |V_{ud}(0^+ \to 0^+)\rangle}{|V_{ud}(\pi \to \mu \nu)| \langle V_{us}(K \to \pi \mu \nu)|},$$

which in the SM is equal to 1. The ratio $\mathcal{B}(K \to \mu \nu)/\mathcal{B}(\pi \to \mu \nu) \sim (V_{us}f_K)/(V_{ud}f_\pi)$ is used to reduce the theoretical uncertainties from the kaon decay constant $f_K$, and from electromagnetic corrections in the decay $K \to \mu \nu$ [119]. The dominant uncertainty in $V_{us}$ from $K \to \pi \mu \nu$ decays stems from the $K \to \pi$ vector form factor at zero momentum transfer, $f_+(0)$, while $V_{ud}$ determined from super-allowed nuclear beta-decays ($0^+ \to 0^+$) is known with very high precision [120].

In the 2HDM of Type-II the dependence of $R_{\ell 23}$ due to charged Higgs exchange is given by [119]

$$R_{\ell 23}^H = \left|1 - \left(1 - m_d/m_s\right) \frac{m_K^2}{m_{H^+}^2} \frac{\tan^2 \beta}{\tan \beta}\right|,$$

where we use $m_d/m_s = 19.5 \pm 2.5$ [60]. Experimentally, a value of $R_{\ell 23}^{\text{exp}} = 1.004 \pm 0.007$ is found [119], where $(f_K/f_\pi)/f_+(0)$ has been taken from lattice calculations. It dominates the uncertainty on $R_{\ell 23}$.

5.1.4 The Semileptonic Decay $B \to D\tau \nu$

Similar to the $B \to \tau \nu$ decay, the semileptonic decay $B \to D\tau \nu$ can be mediated by charged Higgs. We follow the arguments of Ref. [121] and use the ratio $R_{D\tau/e} = \mathcal{B}(B \to D\tau \nu)/\mathcal{B}(B \to D\nu \ell)$ to reduce theoretical uncertainties from hadronic form factors occurring in the predictions of the individual branching fractions. In the Type-II 2HDM the ratio $R_{D\tau/e}$ can be expressed in the following compact form [121]

$$R_{D\tau/e}^H = (0.28 \pm 0.02) \cdot \left[1 + (1.38 \pm 0.03) \cdot \text{Re}(C_{NP}^\tau) + (0.88 \pm 0.02) \cdot |C_{NP}^\tau|^2 \right], \quad (43)$$

where $C_{NP}^\tau = -m_b m_\tau \tan^2 \beta/m_{H^\pm}^2$. As for leptonic decays the 2HDM contribution can either lead to an increase or decrease in the branching fraction. Equation 43 is the result of an integration of the partial width $d\Gamma(B \to D\ell \nu)/dw$, assuming no Higgs contribution to $B \to D\nu \ell$, and where $w = v_B v_D$ with $v_B$ ($v_D$) being the four-velocity of the $B$ ($D$) meson.

The ratio of branching fractions has been measured by BABAR to be $R_{D\tau/e}^{\exp} = 0.42 \pm 0.12_{\text{stat}} \pm 0.05_{\text{syst}}$ [122].

5.2 Results and Discussion

The theoretical predictions of the Type-II 2HDM for the various observables sensitive to corrections from the exchange of charged Higgs bosons have been implemented in a separate library integrated as a plug-in into the Gfitter framework. Exclusion confidence levels have been derived in two ways: (i) for each observable separately, and (ii) in a combined fit.

5.2.1 Separate constraints from individual observables

Constraints in the two-dimensional model parameter plane ($\tan \beta, M_{H^\pm}$) have been derived using the individual experimental measurements and the corresponding theoretical predictions of the Type-II 2HDM. Figure 13 displays the resulting two-sided 68% (yellow/light), 95% (orange)...
5.2 Results and Discussion

Figure 13: Two-sided 68%, 95% and 99% CL exclusion regions obtained respectively from $R^0_b$, $\mathcal{B}(B \to X_s\gamma)$ (top), $\mathcal{B}(B \to \tau\nu)$, $\mathcal{B}(B \to \mu\nu)$ (middle, also showing in the lower middle plots the constraints obtained when using the global CKM fit for the SM prediction of the $B$ leptonic branching fractions [113]), $\mathcal{B}(B \to D\tau\nu)/\mathcal{B}(B \to D\nu)$, and $\mathcal{B}(K \to \mu\nu)/\mathcal{B}(\pi \to \mu\nu)$ (bottom).
and 99% CL (red/dark) excluded regions separately for each of the observables given in Table 5. The confidence levels are derived assuming Gaussian behaviour of the test statistics, and using 1 degree of freedom (cf. discussion in Footnote 6 on page 6). Also indicated in the plots is the 95% CL exclusion limit resulting from the direct searches for a charged Higgs at LEP [103] (hatched area).

The figures show that $R_b$ is mainly sensitive to $\tan\beta$ excluding small values (below $\simeq 1$). $B(B \to X_s\gamma)$ is only sensitive to $\tan\beta$ for values below $\simeq 2$. For larger $\tan\beta$ it provides an almost constant area of exclusion of a charged Higgs lighter than $\simeq 260$ GeV. (All exclusions at 95% CL). For all leptonic observables the 2HDM contribution can be either positive or negative because magnitudes of signed terms are used for the prediction of the branching fractions. This results in a two-fold ambiguity in the $(\tan\beta, m_{H^\pm})$ solution space.

5.2.2 Combined fit

We have performed a global Type-II 2HDM fit combining all the available observables (and using the tree-level SM predictions for the leptonic $B$ decays). We find a minimum $\chi^2$ of 3.9 at $M_{H^\pm} = 860$ GeV and $\tan\beta = 7$. Since the number of effective constraints varies strongly across the $(\tan\beta, M_{H^\pm})$ plane, it is not straightforward to determine the proper number of degrees of freedom to be used in the calculation of the CL – even if the test statistic follows a $\chi^2$ distribution. According to the discussion in Footnote 6 on page 6 we avoid this problem by performing 2000 toy-MC experiments in each scan point to determine the associated p-value. The upper plot of Fig. 14 shows the 95% CL excluded region obtained from the toy-MC analysis of the combined fit (hatched area). Overlaid are the corresponding regions obtained from the individual constraints.

The lower plot of Fig. 14 shows the 68%, 95% and 99% CL excluded regions obtained from the toy-MC analysis of the combined fit (the 95% CL contour being identical to the one in the upper plot). For comparison the 95% CL contours using Prob($\Delta\chi^2, n_{\text{dof}}$) for $n_{\text{dof}} = 1$ and $n_{\text{dof}} = 2$ are also shown. As expected, the $n_{\text{dof}} = 2$ approximation is more accurate in regions where several observables contribute to the combined fit, while $n_{\text{dof}} = 1$ is better when a single constraint dominates over all the others (very small and very large values of $\tan\beta$).

The combination of the constraints excludes the high-$\tan\beta$, low-$M_{H^\pm}$ region spared by the $B \to \tau\nu$ constraint. We can thus exclude a charged-Higgs mass below 240 GeV independently of $\tan\beta$ at 95% confidence level. This limit increases towards larger $\tan\beta$, e.g., $M_{H^\pm} < 780$ GeV are excluded for $\tan\beta = 70$ at 95% CL.

5.2.3 Perspectives

Improvements on the low-energy $B$-meson observables are expected from the KEKB and Belle upgrade program with an initial (final) target of 10 ab$^{-1}$ (50 ab$^{-1}$) integrated luminosity [123–125]. Parallel developments envision the construction of a new SuperB accelerator with similar target luminosities [126]. With respect to the 2HDM analysis, these programs are particularly interesting for the decays $B \to \tau\nu, B \to \mu\nu$ and $B \to D\tau\nu$ whose present branching fraction measurements are statistically dominated. Further improvement can also be expected for the measurement of $B(B \to X_s\gamma)$ with however less prominent effect on the 2HDM parameter constraints due to the size of the theoretical uncertainties. The measurement of the ratio of
Figure 14: Exclusion regions in the \((\tan\beta, M_{H^\pm})\) plane. The top plot shows the 95% CL excluded regions from the constraints given in Table 5, and the toy-MC-based result from the combined fit overlaid. The bottom plot displays the 68%, 95% and 99% CL excluded regions obtained from the combined fit using toy MC experiments. For comparison the 95% CL contours using \(\text{Prob}(\Delta\chi^2, n_{dof})\) for \(n_{dof} = 1\) and \(n_{dof} = 2\) are also shown (see discussion in text).
partial $Z$ widths, $R^0_Z$, could be improved at an ILC running at the $Z$ resonance (GigaZ, cf. Section 4.3). The authors of Ref. [96] estimate a factor of five increase over the current precision, mostly by virtue of the increased statistical yield, and the excellent impact parameter resolution suppressing background from charm quarks.

The LHC experiments will attempt to directly detect signals from charged-Higgs production, either via $t \to bH^\pm$ decays, if $M_{H^\pm} < m_t$, and/or via gluon-gluon and gluon-bottom fusion to $t(b)H^\pm$, and the subsequent decay $H^\pm \to \tau\nu$. The full tan$\beta$ parameter space is expected to be covered for $H^\pm$ lighter than top (a scenario already strongly disfavoured by the current indirect constraints, especially the one from $B(B \to X_s\gamma)$), while the discovery of a heavy $H^\pm$ requires a large tan$\beta$, which rapidly increases with rising $M_{H^\pm}$ [16, 17, 127].

6 Conclusions and Perspectives

The wealth of available precision data at the electroweak scale requires consistent phenomenological interpretation via an overall (global) fit of the Standard Model and beyond. Such fits, mainly determining the top-quark mass, the Higgs-boson mass, the strong coupling constant, and the overall consistency of the model, have been performed by several groups in the past. The fit has sensitivity to confirm electroweak unification and the Brout-Englert-Higgs mechanism [128, 129] of spontaneous electroweak symmetry breaking for the dynamical generation of the fermion and boson masses, while posing problems for alternatives such as Technicolour in its simplest form [130], requiring more involved scenarios. Other theories, like Supersymmetry, are decoupling from the Standard Model if their masses are large. For such models the high energy precision data as well as constraints obtained from rare decays, flavour mixing and CP-violating asymmetries in the $B$ and $K$-meson sectors, the anomalous magnetic moment of the muon, and electric dipole moments of electron and neutron, exclude a significant part of the parameter space. However, the models can be adjusted to become consistent with the experimental data as long as these data agree with the Standard Model predictions.

In this paper, we have revisited the global electroweak fit, and a simple extension of the Higgs sector to two doublets, using the new generic fitting toolkit Gfitter and its corresponding electroweak and 2HDM libraries. We have included the constraints from direct Higgs searches by the LEP and Tevatron experiments in the former fit. Emphasis has been put on a consistent treatment of theoretical uncertainties, using no assumptions other than their respective ranges, and a thorough frequentist statistical analysis and interpretation of the fit results.

Gfitter is an entirely new fitting framework dedicated to model testing in high-energy physics. It features transparent interfaces to model parameters and measurements, theory libraries, and fitter implementations. Parameter caching significantly increases the execution speed of the fits. All results can be statistically interpreted with toy Monte Carlo methods, treating consistently correlations and rescaling due to parameter dependencies.

For the complete fit, including the results from direct Higgs searches, we find for the mass of the Higgs boson the 2$\sigma$ and 3$\sigma$ intervals [114, 145] GeV and [[113, 168] and [180, 225]] GeV, respectively. The corresponding results without the direct Higgs searches in the standard fit are [39, 155] GeV and [26, 209] GeV. Theoretical errors considered in the fit parametrise uncertainties in the perturbative predictions of $M_W$ and $\sin^2\theta_W$, and the renormalisation scheme ambiguity. They contribute with approximately 8 GeV to the total fit error obtained for $M_H$. 

for the standard fit. In a fit excluding the measurement of the top quark mass (but including the direct Higgs searches) we find $m_t = 178.2^{+9.8}_{-4.2}$ GeV, in fair agreement with the experimental world average. Finally, the strong coupling constant to 3NLO order at the $Z$-mass scale is found to be $\alpha_s(M_Z^2) = 0.1193^{+0.0028}_{-0.0027}$ with negligible theoretical error (0.0001) due to the good convergence of the perturbative series at that scale.

We have probed the goodness of the Standard Model fit to describe the available data with toy Monte Carlo simulation. For the fit including the direct Higgs searches it results in a p-value of $0.22 \pm 0.01 - 0.02$, where the first error accounts for the limited Monte Carlo statistics, and the second for the impact of theoretical uncertainties (without these, the p-value is reduced by 0.04). The p-value for the fit without direct Higgs searches is similar (the reduced number of degrees of freedom approximately counteracts the better $\chi^2$ value). The compatibility of the most sensitive measurements determining $M_H$ has been estimated by evaluating the probability for a consistent set of measurements to find a single measurement that increases the overall $\chi^2$ of the global fit by as much as is observed in data, when adding the least compatible measurement (here $A_{FB}^{0,b}$). An analysis with toy MC experiments finds that this occurs in $(1.4 \pm 0.1)\%$ of the cases.

We have analysed the perspectives of the electroweak fit considering three future experimental scenarios, namely the LHC and an international linear collider (ILC) with and without high luminosity running at lower energies (GigaZ), all after years of data taking and assuming a good control over systematic effects. For a 120 GeV Higgs boson, the improved $M_W$ and $m_t$ measurements expected from the LHC would reduce the error on the $M_H$ prediction by up to 20% with respect to the present result. The ILC could further reduce the error by about 25% over the LHC, and – if the hadronic contribution to $\alpha(M_Z^2)$ can be determined with better precision (requiring better hadronic cross section measurements at low and intermediate energies) – a 30% improvement is possible. The largest impact on the fit accuracy can be expected from an ILC with GigaZ option. Together with an improved $\alpha(M_Z^2)$, the present fit error on $M_H$ could be reduced by more than a factor of two. We point out however that, in order to fully exploit the experimental potential, in particular the anticipated improvements in the accuracy of $M_W$, theoretical developments are mandatory. If the Higgs is discovered, the improved electroweak fit will serve as a sensitive test for the Standard Model and its extensions.

By extending the Standard Model Higgs sector to two scalar doublets (2HDM of Type-II), we have studied the experimental constraints on the charged-Higgs mass $M_{H^\pm}$ and on $\tan\beta$, using as input branching fractions of the rare $B$ decays $B \to X_s\gamma$, $B \to \tau\nu$, $B \to \mu\nu$, and $B \to D\nu$, the Kaon decay $K \to \mu\nu$, and the electroweak precision observable $R_b$. Exclusion confidence levels have been derived by carrying out toy experiments for every point on a fine grid of the $(M_{H^\pm}, \tan\beta)$ parameter space. At 95% confidence level we exclude charged Higgs masses $M_{H^\pm} < 240$ GeV for any value of $\tan\beta$, and $M_{H^\pm} < 780$ GeV for $\tan\beta = 70$.

Inputs and numerical and graphical outputs of the Gfitter Standard Model and 2HDM analyses are available on the Gfitter web site: http://cern.ch/gfitter. They will be kept in line with the experimental and theoretical progress. Apart from these update commitments, new theoretical libraries such as the minimal Supersymmetric extension of the Standard Model will be included and analysed.
Acknowledgements

We are indebted to the LEP-Higgs and Tevatron-NPH working groups for providing the numerical results of the direct Higgs-boson searches. We thank Daisuke Nomura and Thomas Teubner for information on their analysis of the hadronic contribution to the running $\alpha(M_Z^2)$. We are grateful to Malgorzata Awramik for providing detailed information about the SM electroweak calculations, and to Bogdan Malaescu for help on the evaluation of theoretical errors affecting the determination of $\alpha_s(M_Z^2)$. We are obliged to the DESY Summer Student Kieran Omahony for his work on the fit automation and the Gfitter web page. We thank the CKMfitter group for providing the best-effort predictions of the rare leptonic $B$ decays used in the 2HDM analysis, and Paolo Gambino, Ulrich Haisch and Mikolaj Misiak for valuable discussions and exchanges regarding the constraints on the 2HDM parameters. Finally, we wish to thank Jérôme Charles, Stefan Schmitt and Stéphane T’Jampens for helpful discussions on statistical problems.
A Standard Model Formulae

This section gives the relevant formulae for the calculation of the electroweak observables used in the global electroweak fit. We discuss the scale evolution of the QED and QCD couplings and quark masses, and give expressions for the electroweak form factors and radiator functions.

A.1 Running QED Coupling

The electroweak fit requires the knowledge of the electromagnetic coupling strength at the Z-mass scale to an accuracy of 1% or better. The evolution of \( \alpha(s) \) versus the mass scale-squared \( s \) is conventionally parametrised by

\[
\alpha(s) = \frac{\alpha(0)}{1 - \Delta \alpha(s)},
\]

following from an all-orders resummation of vacuum polarisation diagrams, sole contributors to the running \( \alpha \). Here \( \alpha = \alpha(0) = 1/137.035999679(94) \) is the fine structure constant in the long-wavelength Thomson limit \([131]\), and the term \( \Delta \alpha(s) \) controls the evolution. It is conveniently decomposed into leptonic and hadronic contributions

\[
\Delta \alpha(s) = \Delta \alpha_{\text{lep}}(s) + \Delta \alpha_{\text{had}}^{(5)}(s) + \Delta \alpha_{\text{top}}(s),
\]

where the hadronic term has been further separated into contributions from the five light quarks (with respect to \( M_Z \)) and the top quark. The leptonic term in (45) is known up to three loops in the \( q^2 \gg m_\ell^2 \) limit \([132]\). The dominant one-loop term at the Z-mass scale reads

\[
\Delta \alpha_{\text{lep}}^{(1\text{-loop})}(M_Z^2) = \alpha \sum_{\ell = e, \mu, \tau} \left( -\frac{5}{9} + \frac{1}{3} \ln \frac{M_Z^2}{m_\ell^2} - 2 \frac{m_\ell^2}{M_Z^2} + \mathcal{O}\left( \frac{m_\ell^4}{M_Z^4} \right) \right) \approx 314.19 \cdot 10^{-4}.
\]

Adding the sub-leading loops gives a total of \( \Delta \alpha_{\text{lep}}(s) = 314.97 \cdot 10^{-4} \), with negligible uncertainty.\(^{38}\)

The hadronic contribution for quarks with masses smaller than \( M_Z \) cannot be obtained from perturbative QCD alone because of the low energy scale involved. Its computation relies on analyticity and unitarity to express the photon vacuum polarisation function as a dispersion integral involving the total cross section for \( e^+ e^- \) annihilation to hadrons at all time-like energies above the two-pion threshold. In energy regions where perturbative QCD fails to locally predict the inclusive hadronic cross section, experimental data is used. The accuracy of the calculations has therefore followed the progress in the quality of the corresponding data. Recent calculations improved the precision by extending the use of perturbative QCD to energy regions of relatively low scales, benefiting from global quark-hadron duality. For the fits in this paper we use the most recent value, \( \Delta \alpha_{\text{had}}^{(5)}(M_Z^2) = (276.8 \pm 2.2) \cdot 10^{-4} \), from Ref. [62]. The error is dominated by systematic uncertainties in the experimental data used to calculate the dispersion integral. A small part of the error, 0.14 \( \cdot 10^{-4} \), is introduced by the uncertainty in \( \alpha_s(s) \) (the authors of [62] used the value \( \alpha_s(M_Z^2) = 0.1176 \pm 0.0020 \) [133]). We include this dependence in the fits via the parameter rescaling mechanism implemented in Gfitter (cf. Section 3).

\(^{38}\)While the two-loop leptonic contribution of 0.78 \( \cdot 10^{-4} \) is significant (roughly one third of the uncertainty in the hadronic contribution), the third order term, 0.01 \( \cdot 10^{-4} \), is very small.
The small top-quark contribution at $M_Z^2$ up to second order in $\alpha_S$ reads [134–137] to
\[
\Delta\alpha_{\text{top}}(M_Z^2) = -\frac{4}{45} \frac{\alpha M_Z^2}{m_t^2} \left\{ 1 + 5.062 a_S^{(5)}(\mu^2) + \left( 28.220 + 9.702 \ln \frac{\mu^2}{m_t^2} \right) (a_S^{(5)}(\mu^2))^2 \right\}^2 
+ \frac{M_Z^2}{m_t^2} \left[ 0.1071 + 0.8315 a_S^{(5)}(\mu^2) + \left( 6.924 + 1.594 \ln \frac{\mu^2}{m_t^2} \right) (a_S^{(5)}(\mu^2))^2 \right] \right\},
\]
\approx -0.7 \cdot 10^{-4},
\]
where the short-hand notation $a_S = \alpha_S/\pi$ is used, and where $a_S^{(5)}$ is the strong coupling constant for five active quark flavors, and $\mu$ is an arbitrary renormalisation scale, chosen to be $\mu = M_Z$ in the fit.

The uncertainty on $\alpha(M_Z^2)$ is dominated by the hadronic contribution $\Delta\alpha_{\text{had}}^{(5)}(M_Z^2)$, which is a floating parameter of the fit constrained to its phenomenological value. The errors due to uncertainties in $M_Z$, $m_t$ and $\alpha_S$ are properly propagated throughout the fit. Other uncertainties are neglected.

A.2 QCD Renormalisation

Like in QED, the subtraction of logarithmic divergences in QCD is equivalent to renormalising the coupling strength ($\alpha_S \equiv g_s^2/4\pi$), the quark masses ($m_q$), etc., and the fields in the bare (superscript $B$) Lagrangian such as $\alpha_S^B = s^2 Z \alpha_S$, $m_q^B = s^2 Z m_q$, etc. Here $s$ is the renormalisation scale-squared, $\varepsilon$ the dimensional regularisation parameter, and $Z$ denotes a series of renormalisation constants obtained from the generating functional of the bare Green’s function.

Renormalisation at scale $\mu$ introduces a differential renormalisation group equation (RGE) for each renormalised quantity, governing its running. All formulae given below are for the modified minimal subtraction renormalisation scheme ($\overline{\text{MS}}$) [138, 139].

A.2.1 The Running Strong Coupling

The RGE for $\alpha_S(\mu^2)$ reads
\[
\frac{d\alpha_S}{d \ln \mu^2} = \beta(\alpha_S) = -\beta_0 \alpha_S^2 - \beta_1 \alpha_S^3 - \beta_2 \alpha_S^4 - \beta_3 \alpha_S^5 - \ldots ,
\]
(48)

The perturbative expansion of the $\beta$-function is known up to four loops [140] (and references therein), with the coefficients
\[
\beta_0 = \frac{1}{4\pi} \left[ 11 - \frac{2}{3} n_f \right],
\]
(49)
\[
\beta_1 = \frac{1}{(4\pi)^2} \left[ 102 - \frac{38}{3} n_f \right],
\]
(50)
\[
\beta_2 = \frac{1}{(4\pi)^3} \left[ \frac{2857}{2} - \frac{5033}{18} n_f + \frac{325}{54} n_f^2 \right],
\]
(51)
\[
\beta_3 = \frac{1}{(4\pi)^4} \left[ \left( \frac{149753}{6} + 3564 \zeta_3 \right) n_f + \left( \frac{1078361}{162} + 6508 \frac{27}{27} \zeta_3 \right) n_f^2 + \left( \frac{50065}{162} + 6472 \frac{81}{81} \zeta_3 \right) n_f^3 + \left( \frac{1093}{729} \zeta_3 \right) n_f^4 \right],
\]
(52)
where \( n_f \) is the number of active quark flavours with masses smaller than \( \mu \), and where \( \zeta_3 \simeq 1.2020569 \). Solving Eq. (48) for \( \alpha_s \) introduces a constant of integration, \( \Lambda^{(n_f)} \), with dimension of energy. The solution of the RGE in the ultraviolet limit reads \([141, 142]\)

\[
\alpha_s (\mu^2) = \frac{1}{\beta_0} L \left\{ 1 - \frac{\beta_1}{\beta_0} \ln L + \frac{1}{\beta_0^2 L^2} \left[ \frac{\beta_2}{\beta_0} (\ln^2 L - \ln L - 1) + \frac{\beta_3}{\beta_0} \right] + \frac{1}{\beta_0^4 L^3} \left[ \frac{\beta_2^2}{\beta_0} (\ln^3 L - 3 \ln L - 2) - 3 \frac{\beta_1 \beta_2}{\beta_0^2} \ln L + \frac{\beta_1 \beta_3}{\beta_0^3} \right] \right\}, \tag{53}
\]

where \( L = 2 \ln (\mu/\Lambda^{(n_f)}) \gg 1 \).

As \( \alpha_s \) evolves it passes across quark-flavour thresholds. Matching conditions at these thresholds connect \( \alpha_s^{(n_f)} \) of the full theory with \( n_f \) flavors to the effective strong coupling constant \( \alpha_s^{(n_f-1)} \), where the heaviest quark decouples. The coupling constant of the full theory is developed in a power series of the coupling constant of the effective theory with coefficients that depend on \( x = 2 \ln (\mu/\overline{m}_q) \) \([141, 143-145]\):

\[
\alpha_s^{(n_f)} = \alpha_s^{(n_f-1)} \left[ 1 + C_1(x) \left( \alpha_s^{(n_f-1)} \right) + C_2(x) \left( \alpha_s^{(n_f-1)} \right)^2 + C_3(x) \left( \alpha_s^{(n_f-1)} \right)^3 \right], \tag{54}
\]

with \( \alpha_s = \alpha_s/\pi \) (recalled), and

\[
C_1(x) = \frac{x}{6}, \quad C_2(x) = c_{2,0} + \frac{19}{24} x + \frac{x^2}{36}, \quad C_3(x) = c_{3,0} + \frac{241}{54} + \frac{13}{4} c_{2,0} - \left( \frac{325}{1728} + \frac{c_{2,0}}{6} \right) n_f x + \frac{511}{576} x^2 + \frac{x^3}{216}. \tag{55}
\]

The integration coefficients \( c_{2,0} \) computed in the \( \overline{\text{MS}} \) scheme at the scale of the quark masses are

\[
c_{2,0} = -\frac{11}{72}, \quad c_{3,0} = \frac{82043}{27648} \zeta_3 - \frac{575263}{124416} + \frac{2633}{31104} n_f. \tag{56}
\]

The solution of the RGE (48) at arbitrary scale requires \( \alpha_s \) to be known at some reference scale, for which the \( Z \) pole is commonly chosen. Three evolution procedures are implemented in Gfitter, which lead to insignificant differences in the result. The first uses numerical integration of the RGE with a fourth-order Runge-Kutta method. The second (the one chosen for this paper) determines \( \Lambda^{(5)} \) at \( M_Z \) by numerically evaluating the root of Eq. (53), and the values for \( \Lambda^{(n_f \neq 5)} \) are obtained via the matching conditions. Both methods use \( \alpha_s(M_Z^2) \) as floating parameter in the fit. In the third approach, \( \Lambda^{(5)} \) is directly determined by the fit without explicit use of \( \alpha_s(M_Z^2) \).

### A.2.2 Running Quark Masses

The \( \overline{\text{MS}} \) RGE for massive quarks is governed by the \( \gamma \)-function defined by

\[
\frac{1}{\beta_0} \frac{d \overline{m}_q}{\ln \mu^2} = \gamma (\alpha_s) = -\gamma_0 \alpha_s - \gamma_1 \alpha_s^2 - \gamma_2 \alpha_s^3 - \gamma_3 \alpha_s^4 - \ldots. \tag{57}
\]

Its perturbative expansion has been computed to four loops \([146]\) (and references therein), which for the \( c \) and \( b \)-quark flavours reads \([146]\)

\[
\overline{m}_c (\mu^2) = \tilde{m}_c \alpha_s^{12/25} \left[ 1 + 1.0141 a_s + 1.3892 a_s^2 + 1.0905 a_s^3 \right],
\]
\[
\overline{m}_b (\mu^2) = \tilde{m}_b \alpha_s^{12/23} \left[ 1 + 1.1755 a_s + 1.5007 a_s^2 + 0.1725 a_s^3 \right]. \tag{58}
\]
The scale dependence of $\bar{m}_q(\mu^2)$ is given by the scale dependence of $a_s = a_s(\mu^2)$. The renormalisation group independent mass parameters $\bar{m}_q$ are determined from the measured quark masses at fixed scales (cf. Table 1).

### A.3 Electroweak Form Factors

The calculation of the electroweak form factors for lepton or quark flavours $f$, $\rho^f_Z$ and $\kappa^f_Z$, absorbing the radiative corrections (cf. Eqs. 11–13), follows the ZFITTER procedure [6]. It includes two-loop electroweak corrections [6, 13, 42, 147–150]. We use the intermediate on-shell mass scheme [6], which lies between OMS-I and OMS-II. These latter two schemes are used to estimate the uncertainty arising from the renormalisation scheme ambiguity (see [55] for more information). The form factors in the intermediate scheme are given by

$$\rho^f_Z = \frac{1 + \delta \rho^f_{\text{rem}}}{1 + \delta \hat{\rho}^c(G) (1 - \Delta F^G_{\text{rem}})} + \delta \rho^f_{\text{rem}} G^2, \quad (59)$$

$$\kappa^f_Z = \left(1 + \delta \kappa^f_{\text{rem}}\right) \left[ 1 - \frac{c^2_W}{2 s^2_W} \delta \hat{\rho}^c(G) (1 - \Delta F^G_{\text{rem}}) \right] + \delta \kappa^f_{\text{rem}} G^2, \quad (60)$$

where the superscript $(G)$ stands for the inclusion of all known terms, whereas $[G] = G + \alpha_s G$ includes the electroweak one-loop corrections together with all known orders in the strong coupling constant. These QCD corrections are taken from [151]. The parameter $\delta \hat{\rho}^c(G)$ contains all known corrections to the Veltman parameter, defined by the ratio of effective couplings where $\delta \hat{\rho}^c(G)$ includes the electroweak one-loop corrections together with all known orders in the strong coupling constant. These QCD corrections are taken from [151]. The parameter $\delta \hat{\rho}^c(G)$ contains all known corrections to the Veltman parameter, defined by the ratio of effective couplings

where $N^f_{\ell} = 3(1)$ is the colour factor, $s^2_w = \sin^2 \theta_w$ and $c^2_w = \cos^2 \theta_w$, and where $\Delta \rho^F_w$ is given by

$$\Delta \rho^F_w = \frac{1}{M^2_W} \left[ \Sigma^F_{W W}(0) - \Sigma^F_{W W}(M^2_W) \right]. \quad (63)$$

The terms $\Sigma^F_{W W}(0)$ and $\Sigma^F_{W W}(M^2_W)$ are the $W$ boson self energies discussed below.

For the purpose of illustration we give the formulae for the one-loop corrections of the electroweak form factors at the $Z$ pole for vanishing external fermion masses [154]:

$$\delta \rho^f_{\text{rem}} = \frac{\alpha}{4 \pi s^2_w} \left[ \Sigma'_{zz}(M^2_Z) - \Delta \rho^F_Z - \frac{11}{2} - \frac{5}{8} c^2_w (1 + c^2_w) - \frac{9 c^2_w}{4 s^2_w} \ln c^2_w + 2 u_f \right], \quad (64)$$

$$\delta \kappa^f_{\text{rem}} = \frac{\alpha}{4 \pi s^2_w} \left[ -\frac{c^2_w}{s^2_w} \Delta \rho^F + \Pi^F_{Z \gamma}(M^2_Z) + \frac{s^4_w}{c^2_w} Q^2 e^2 \Pi^F_{V Z}(M^2_Z) - u_f \right], \quad (65)$$
where
\[ u_f = \frac{1}{4c_W^2} \left[ 1 - 6|Q_f|s_w^2 + 12Q_f^2s_w^4 \right] V_{1Z}(M_Z^2) + \left[ \frac{1}{2} - c_W^2 - |Q_f|s_w^2 \right] V_{1W}(M_Z^2) + c_W^2 V_{2W}(M_Z^2) , \]
\[ \Delta \rho^F_Z = \frac{1}{M_W^2} \left[ \Sigma^F_{WW}(0) - \Sigma^F_{Zz}(M_Z^2) \right] . \]

The term \( \Sigma^F_{Zz}(M_W^2) \) is the Z boson self energy. The vertex functions in the chiral limit are given by [13]
\[ V_{1V}(s) = -\frac{7}{2} - 2R_V - (3 + 2R_V) \ln(-\bar{R}_V) + 2(1 + R_V)^2 \left[ L_i(1 + \bar{R}_V) - L_i(1) \right] , \quad (66) \]
\[ V_{2W}(s) = -\frac{1}{6} - 2R_W - \left( \frac{7}{6} + R_W \right) \frac{L_W W(s)}{s} + 2R_W (R_W + 2) F_3(s, M_W^2) , \quad (67) \]
where \( L_i \) is the dilogarithm function, and where \( \bar{R}_V = R_V - i\gamma_V, \gamma_V = M_V \Gamma_V/s, \) and \( R_V = M_V^2/s \). The \( Z-\gamma \) mixing function in Eq. (65) is given by
\[ \Pi^F_{Z\gamma}(M_Z^2) = 2 \sum_f N_c^f |Q_f| v_f I_3(-s; m_f^2, m_f^2) , \quad (68) \]
where \( v_f = 1 - 4Q_f^2 s_w^2 \), and where the index \( f \) runs over all fundamental fermions. The integrals \( F_3 \) in (67) and \( I_3(Q^2; M_V^2, M_Z^2) \) in (68) are given in Appendices C and D of Ref. [155].

For the two-loop corrections to the electroweak form factors, \( \delta \rho_{em}^{fG^2} \) and \( \delta \kappa_{em}^{fG^2} \) in Eqs. (59) and (60), the interested reader is referred to the original literature [6, 13, 42, 147–150]. Because of missing two-loop corrections to the form factors \( \rho^b_Z \) and \( \kappa^b_Z \) occurring in \( Z \to b\bar{b} \), an approximate expression is used, which includes the full one-loop correction and the known leading two-loop terms \( \propto m_t^2 \). Non-universal top contributions [6, 156, 157] must be taken into account in this channel due to a CKM factor close to one and the large mass difference of bottom and top quarks
\[ \tau_b = -2x_t \left[ 1 - \frac{\pi}{3} \beta_s(m_t^2) + \frac{G_F m_t^2}{8\pi^2 \sqrt{2}} \tau^{(2)}(m_t^2/M_Z^2) \right] , \quad (69) \]
where the function \( \tau^{(2)}(m_t^2/M_Z^2) \) is given in [156]. Since the first term in Eq. (69) represents one-loop corrections, it must be subtracted from the universal form factors to avoid double-counting. Let \( \rho^b \) and \( \kappa^b \) be these corrected form factors (cf. Refs. [6, 156, 157] for the correction procedure), the form factors beyond one-loop are obtained by \( \rho_b = \rho^b_b, \kappa_b = \kappa^b_b(1 + \tau_b)^{-1} \).
A.3.1 Self-Energies of W and Z Boson

The W and Z boson self-energies $\Sigma_{WW}^F$ and $\Sigma_{ZZ}^F$ and on-shell derivative $\Sigma_{zz}^F$ are the sums of bosonic and fermionic parts. The bosonic parts read [13, 158]

$$\Sigma^\text{Bos,F}_{WW}(0) = \frac{5c_w^4}{8} + \frac{17}{4} + \frac{5}{8c_w^2} - \frac{r_W}{8} + \left(\frac{9}{4} + \frac{3}{4c_w^2} - \frac{3}{s_w^2}\right) \ln c_w^2 + \frac{3r_W}{4(1-r_W)} \ln r_W,$$

(70)

$$\Sigma^\text{Bos,F}_{WW}(M_W^2) = -\frac{157}{9} + \frac{23}{12c_w^2} + \frac{1}{12c_w^2} - \frac{r_W}{2} + \frac{r_W^2}{12} + \frac{1}{c_w^2} \left(\frac{7}{2} + \frac{7}{12c_w^2} + \frac{1}{24c_w^2}\right) \ln c_w^2$$

$$+ r_W \left(\frac{3}{4} - \frac{r_W}{4} - \frac{r_W^2}{24}\right) \ln r_W + \left(\frac{1}{2} - \frac{r_W}{6} + \frac{r_W^2}{24}\right) L_W H(M_W^2)\frac{M_Z^2}{M_W^2},$$

(71)

$$\Sigma^\text{Bos,F}_{zz}(M_Z^2) = -8c_w^4 - \frac{34c_w^2}{3} + \frac{35}{18} \left(1 + \frac{1}{c_w^6}\right) - \frac{r_W}{2} + \frac{r_W^2}{12c_w^2} + r_W \left(\frac{3}{4} - \frac{r_W}{4} - \frac{r_W^2}{24}\right) \ln r_Z$$

$$+ \frac{5 \ln c_w^2}{6c_w^2} + \left(\frac{1}{2} - \frac{r_Z}{6} + \frac{r_Z^2}{24}\right) L_Z H(M_Z^2)\frac{M_W^2}{M_Z^2},$$

(72)

$$\Sigma^\text{Bos,F}_{zz}(M_Z^2) = -4c_w^4 + \frac{17c_w^2}{3} - \frac{23}{9} + \frac{5}{18c_w^2} \frac{r_W}{2} + \frac{r_W^2r_Z}{6} + r_W \left(\frac{3}{4} + \frac{3r_Z}{8} - \frac{r_Z^2}{12}\right) \ln r_Z$$

$$- \frac{1}{12c_w^2} \ln c_w^2 + \frac{\ln r_Z}{c_w^2} + \left(-\frac{c_w^6}{6} + \frac{7c_w^4}{12} - \frac{17c_w^2}{12}\right) \frac{L_W W(M_Z^2)}{M_W^2}$$

$$+ \left(\frac{1}{2} - \frac{r_Z}{24} + \frac{r_Z^2}{12} + \frac{1}{2(2r_Z - 4)}\right) \frac{L_Z H(M_Z^2)}{M_Z^2},$$

(73)

where the shorthand notation $r_W = M_H^2/M_W^2$ and $r_Z = M_H^2/M_Z^2$ has been used. The function $L_{V_1V_2}(s) = L(-s; M_H^2, M_Z^2)$ is defined in Eq. (2.14) of Ref. [159].

The fermionic parts read [13, 158]

$$\Sigma^\text{Fer,F}_{WW}(M_W^2) = \sum_{f=f_u,f_d} N_f \left[ -\frac{2s}{M_W^2} I_3(\ldots) + \frac{m_f^2}{M_W^2} I_1(\ldots) + \frac{m_f^2}{M_W^2} I_4(-s; m_{f_d}, m_{f_u}) \right],$$

(74)

$$\Sigma^\text{Fer,F}_{zz}(M_Z^2) = \frac{1}{2c_w^2} \sum_f N_f \left[ -\frac{s}{M_Z^2} \left(1 + v_f^2\right) I_3(-s; m_f^2, m_f^2) + \frac{m_f^2}{M_Z^2} I_0(-s; m_f^2, m_f^2) \right],$$

(75)

$$\sum^\text{Fer,F}_{zz}(M_Z^2) = -\sum_f N_f \left\{ \frac{r_f}{2} \left[ 1 - r_f M_W^2 \mathcal{F}(-M_Z^2, m_f^2, m_f^2) \right] + \frac{1}{6c_w^2} (1 + v_f^2) \right\}$$

$$\times \left[ \frac{1}{2} \ln(r_f c_w^2) + r_f c_w^2 \left(-\frac{1}{4c_w^2} + \frac{r_f}{2} - \frac{r_f c_w^2}{2}\right) M_W^2 \mathcal{F}(-M_Z^2, m_f^2, m_f^2) \right],$$

(76)

with $r_f = m_f^2/M_W^2$ and $v_f = 1 - 4Q_f s_w^2$ (recalled from above), and where $(\ldots)$ in Eq. (74) stands for $(-s; m_f^2, m_f^2)$. The sums are taken over all fundamental up-type and down-type fermions of all $SU(2) \otimes U(1)$ doublets with masses $m_{f_u}$ and $m_{f_d}$, respectively. The integrals $I_n(Q^2; M_f^2, M_f^2)$ and $\mathcal{F}$ are given in Appendix D of Ref. [155].
A.4 Radiator Functions

The radiator functions $R_q^v(s)$ and $R_q^a(s)$ absorb the final state QED and QCD corrections to the vector and axial-vector currents in hadronic $Z$ decays. They also contain mixed QED $\otimes$ QCD corrections and finite quark-mass corrections expressed in terms of running masses. The following formulae are taken from [42]. They have been updated to take into account results from the recent 3NLO calculation of the massless QCD Adler function [14] (represented by the coefficient $C_{04}$).

\[ R_q^v(s) = 1 + \frac{3}{4} Q_q^2 \frac{\alpha(s)}{\pi} a_s(s) + \frac{1}{4} Q_q^2 \frac{\alpha(s)}{\pi} a_s(s) + \delta C_{05} a_s^2(s) + \frac{m_q^2(s) + \overline{m}_q^2(s)}{s} C_{23} a_s^3(s) + \frac{m_q^2(s)}{s} [C_{22}^V a_s(s) + C_{22}^V a_s^2(s)] + \frac{m_q^2(s)}{s^2} \left[ C_{24}^V a_s(s) + C_{24}^V a_s^2(s) + C_{24}^V a_s^3(s) \right] + \frac{m_q^2(s)}{s^2} \left[ C_{24}^V a_s(s) + C_{24}^V a_s^2(s) \right] + \left[ C_{24}^V a_s(s) + C_{24}^V a_s^2(s) \right] + \frac{12}{s^2} \frac{m_q^2(s)}{s^2} a_s^2(s) - \frac{16}{s^2} \left[ 8 + \frac{16}{27} \left[ 155 + 6 \ln \left( \frac{m_q^2(s)}{s^2} \right) \right] a_s(s) \right], \] (77)

\[ R_q^a(s) = 1 + \frac{3}{4} Q_q^2 \frac{\alpha(s)}{\pi} a_s(s) + \frac{1}{4} Q_q^2 \frac{\alpha(s)}{\pi} a_s(s) + \delta C_{05} a_s^2(s) + \frac{m_q^2(s) + \overline{m}_q^2(s)}{s} C_{23} a_s^3(s) + \frac{m_q^2(s)}{s} [C_{22}^A a_s(s) + C_{22}^A a_s^2(s) + C_{22}^A a_s^3(s)] + \frac{m_q^2(s)}{s^2} \left[ C_{24}^A a_s(s) + C_{24}^A a_s^2(s) + C_{24}^A a_s^3(s) \right] - \frac{10}{s^2} \frac{m_q^2(s)}{s^2} \left[ \frac{8}{81} + \frac{1}{54} \ln \left( \frac{m_q^2(s)}{s^2} \right) \right] a_s^2(s) + \frac{m_q^2(s)}{s^2} \left[ C_{24}^A a_s(s) + C_{24}^A a_s^2(s) + C_{24}^A a_s^3(s) \right] - \frac{12}{s^2} \frac{m_q^2(s)}{s^2} a_s^2(s), \] (78)

where the finite quark-mass corrections are retained for charm and bottom quarks only, \textit{i.e.}, all lighter quarks are taken to be massless. This restricts the validity of the above formula...
to energies well above the strange-pair and below the top-pair production thresholds, which is sufficient for our use. The mass $m'_q$ denotes the other quark mass, i.e., it is $\overline{m}_b$ if $q = c$ and $\overline{m}_c$ if $q = b$. The running of the quark masses is computed in the $\overline{\text{MS}}$ scheme according to Eq. (58). The two parameters $\delta_{T(4)}$ and $\delta_{C_{05}}$ represent the next unknown coefficients in the perturbative expansion. They are treated as theoretical errors within the $R$ fit scheme, and vary within the bounds obtained when assuming a geometric growth of the perturbative coefficients with the perturbative order, i.e., for a coefficient $H$ one has $\delta_H = (H_{n-1}/H_{n-2}) \cdot H_{n-1}$.

The expressions for the fixed-order perturbative coefficients $C_{ij}^{(V/A)}$ in Eqs. (77) and (78) are given below.

**Massless non-singlet corrections [14, 160–163]:**

\[
C_{02} = \frac{365}{24} - 11 \zeta(3) + \left( \frac{11}{12} + \frac{2}{3} \zeta(3) \right) n_f ,
\]

\[
C_{03} = \frac{87029}{288} - \frac{121}{8} \zeta(2) - \frac{1103}{4} \zeta(3) + \frac{275}{6} \zeta(5)
+ \left( -\frac{7847}{216} + \frac{11}{6} \zeta(2) - \frac{262}{9} \zeta(3) - \frac{25}{3} \zeta(5) \right) n_f
+ \left( \frac{151}{162} - \frac{1}{18} \zeta(2) - \frac{19}{27} \zeta(3) \right) n_f^2 ,
\]

\[
C_{04} = -156.61 + 18.77 n_f - 0.7974 n_f^2 + 0.0215 n_f^3 ,
\]

which for $n_f = 5$ take the values $C_{02} = 1.40923$, $C_{03} = -12.7671$ and $C_{04} = -80.0075$, exhibiting satisfactory convergence given that $\alpha_s(M_Z^2)/\pi \simeq 0.04$.

**Quadratic massive corrections [164]:**

\[
C_{23} = -80 + 60 \zeta(3) + \left( \frac{32}{9} - \frac{8}{3} \zeta(3) \right) n_f ,
\]

\[
C_{21}^V = 12 ,
\]

\[
C_{22}^V = \frac{253}{2} - \frac{13}{3} n_f ,
\]

\[
C_{23}^V = 2522 - \frac{855}{2} \zeta(2) + \frac{310}{3} \zeta(3) - \frac{5225}{6} \zeta(5)
+ \left[ -\frac{4942}{27} + 34 \zeta(2) - \frac{394}{27} \zeta(3) + \frac{1045}{27} \zeta(5) \right] n_f
+ \left[ \frac{125}{54} - \frac{2}{3} \zeta(2) \right] n_f^2 ,
\]

\[
C_{20}^A = -6 ,
\]

\[
C_{21}^A = -22 ,
\]

\[
C_{22}^A = -\frac{8221}{24} + 57 \zeta(2) + 117 \zeta(3) + \left[ \frac{151}{12} - 2 \zeta(2) - 4 \zeta(3) \right] n_f ,
\]

\[
C_{23}^A = -\frac{4544045}{864} + 1340 \zeta(2) + \frac{118915}{36} \zeta(3) - 127 \zeta(5)
+ \left[ \frac{71621}{162} - \frac{209}{2} \zeta(2) - 216 \zeta(3) + 5 \zeta(4) + 55 \zeta(5) \right] n_f
+ \left[ -\frac{13171}{1944} + \frac{16}{9} \zeta(2) + \frac{26}{9} \zeta(3) \right] n_f^2 .
\]
Quartic massive corrections \cite{164}:

\begin{align}
C_{42} &= \frac{13}{3} - 4 \zeta(3), \\
C_{40}^V &= -6, \\
C_{41}^V &= -22, \\
C_{42}^V &= -\frac{3029}{12} + 162 \zeta(2) + 112 \zeta(3) + \left[\frac{143}{18} - 4 \zeta(2) - \frac{8}{3} \zeta(3)\right] n_f, \\
C_{42}^{V, L} &= -\frac{11}{2} + \frac{1}{3} n_f, \\
C_{40}^A &= 6, \\
C_{41}^A &= 10, \\
C_{42}^A &= \frac{3389}{12} - 162 \zeta(2) - 220 \zeta(3) + \left[-\frac{41}{6} + 4 \zeta(2) + \frac{16}{3} \zeta(3)\right] n_f, \\
C_{42}^{A, L} &= -\frac{7}{2} - \frac{7}{3} n_f. 
\end{align}

Power suppressed top-mass correction \cite{164}:

\begin{equation}
C_2^t(x) = x \left(\frac{44}{675} - \frac{2}{135} \ln x\right).
\end{equation}

Singlet axial-vector corrections \cite{164}:

\begin{align}
T^{(2)}(x) &= -\frac{37}{12} + \ln x + \frac{7}{81} x + 0.0132 x^2, \\
T^{(3)}(x) &= -\frac{5075}{216} + \frac{23}{6} \zeta(2) + \zeta(3) + \frac{67}{18} \ln x + \frac{23}{12} \ln^2 x.
\end{align}

Singlet vector correction \cite{164}:

\begin{equation}
R^h_{\nu}(s) = \left(\sum_f v_f\right)^2 (-0.41317) a_3^\nu(s).
\end{equation}
