ABSTRACT

A search for direct photons produced in proton-proton collisions has been performed at two $\sqrt{s}$ values at the CERN Intersecting Storage Rings (ISR). It is found that direct photons are produced preferentially with no accompanying particles on the same side. On the away side, the ratio of positive to negative high-$x_E$ particles is found to be higher for high transverse momentum direct-photon events, than for high transverse momentum neutral-meson events.
In our previous publication [1], a measurement of direct-photon production in p-p collisions at $\sqrt{s} = 62.4$ GeV was described. This letter reports results obtained by analysis of data at $\sqrt{s} = 44$ GeV, and a study of the correlation of charged and neutral particles with the direct photons.

The apparatus [1-5] and method [1] have been discussed elsewhere. The experiment used two lead-glass arrays to trigger on high-$p_T$ single photons and neutral mesons decaying into photons. A statistical separation between these two kinds of particles is achieved by measuring the fraction of particles that did not convert when passing through a 1.0 radiation length converter (the coil of a superconducting solenoid magnet), and contrasting it with the fraction expected if all the particles were neutral mesons, and the fraction expected if all were single photons. The integrated luminosities, energies, and trigger thresholds used are shown in table 1. The results (fig. 1) are expressed in terms of $f_\gamma$, which is the ratio of the number of events ascribed to direct photons to the total number of events. The errors shown are statistical only. There is a further ±5% systematic error of which 3% is $\sqrt{s}$ dependent. The data suggest an increase of $f_\gamma$ as $\sqrt{s}$ decreases. A comparison with the data of ref. 6 at $\sqrt{s} = 63$ GeV was presented in ref. 1. For $\sqrt{s} = 44$ GeV and $5 < p_T < 8$ GeV/c, $f_\gamma = 9.6 \pm 1.5\%$. When the data of ref. 6 are restated in terms of $f_\gamma$, their result at the same $\sqrt{s}$ and $p_T$ is $f_\gamma \approx 0.14$.

For the study of correlations, the data from the two $\sqrt{s}$ values are combined in order to improve the statistical accuracy of the subsequent analysis. High-$p_T$ mesons are usually produced as part of a jet, and are observed in conjunction with other particles emitted at similar azimuth and rapidity. On the other hand, in most models [7], direct photons are preferentially produced unaccompanied by such particles. Accordingly, the data have been divided into two classes of events: a) those which have at least one charged or neutral particle, of $p_T > 0.3$ GeV/c, other than the trigger in the trigger hemisphere ($|\Delta \phi| < 90^\circ$ about the trigger direction and pseudorapidity $\eta$ in the range $-0.7 < \eta < 0.7$), and b) those which do not. The resulting values of $f_\gamma$ are shown in figs. 2a,b for the
two classes of events. The values of $f_{\gamma}$ for the accompanied trigger particles are clearly lower than those for the unaccompanied trigger particles. For trigger transverse momenta $p_{T\text{Trig}}$ in the range 6 to 10 GeV/c, $17.0 \pm 2.0\%$ (statistical) of the unaccompanied sample may be attributed to direct photons, whereas for the accompanied sample the single photon fraction is $0.7 \pm 1.2\%$. For transverse momenta above 10 GeV/c, the single-photon content of the unaccompanied and accompanied samples is $33.0 \pm 6.0\%$ and $16.0 \pm 5.0\%$ respectively. This result suggests that direct photons are due mainly to processes such as $q\bar{q} \rightarrow \gamma g$ and $gq \rightarrow \gamma q$ which result in photons that are unaccompanied by other particles in the trigger hemisphere, rather than processes, for example quark bremsstrahlung, in which the photon would be accompanied by particles resulting from quark fragmentation. This enhancement of direct-photon production in a sample of unaccompanied trigger particles is in qualitative agreement with other ISR results [8].

If the process yielding direct photons is $gq \rightarrow \gamma q$, then it is expected from theory that a $u$ quark will be involved eight times more often than a $d$ quark because of the quark charges and abundances in the proton. This large excess with a positively charged parent quark should be reflected in the charge of the jet opposite to the direct photon [9]. This possibility has been investigated by measuring the charge ratio, $R = \frac{p_{T\text{Track}}^{+}}{p_{T\text{Track}}^{-}}$, where $p_{T\text{Track}}$ is the transverse momentum of the charged particle. It should be noted that the ratio $R$ is sensitive to a small difference in the relative $p_{T}$ scales of positive and negative particles, such as that resulting from a small misalignment of the drift chambers. An estimate of the possible systematic error on the charge ratio introduced by such effects was obtained by measuring the mean momentum of positrons ($p_{e^+}$) and electrons ($p_{e^-}$) from a sample of 70 upsilons obtained in the same apparatus and at the same time as the direct-photon data [2]. The results were $(p_{e^+}) = 5.60 \pm 0.30$ GeV/c, $(p_{e^-}) = 5.65 \pm 0.37$ GeV/c. Note that these momenta are similar to or higher than the momenta of most charged particles used in the measurement of $R$. Given the $x_{E}$ distribution of the charged particles
and the accuracy in the measurement of \((p_{e^+})\) and \((p_{e^-})\), the effect on \(R\) of a possible misalignment of the drift chambers is estimated to be \(\Delta R/R < 0.2\). In addition, the charge ratio in the jet recoiling against a sample of triggers consisting mostly of \(\pi^0\)'s is found to be in very good agreement with the charge ratio of Clark et al. [10]: for instance, for \(p_{T\text{trig}} > 5\ \text{GeV/c}\) and \(0.3 < x_E < 0.5\), \(R = 1.25 \pm 0.08\), to be compared to \(1.30 \pm 0.09\) as measured by ref. 9.

Two subsets of the data were used to measure \(R\). Subset a), enriched in single-photon content by requiring the trigger particle not to have converted and to be unaccompanied by another particle in the trigger hemisphere, consisted of 39% single photons and 61% neutral mesons. Subset b), enriched in neutral-meson content by requiring the trigger particle to have converted and to be accompanied by another particle in the trigger hemisphere, consisted of only 4% single photons and 96% neutral mesons. It can be seen (figs. 3a,b) that the direct-photon-enhanced sample has a higher charge ratio than the neutral-meson sample for \(x_E > 0.3\) and \(p_{T\text{trig}} > 5\ \text{GeV/c}\). From the values of \(R\) shown in fig. 3, the values of \(f_\gamma\) shown in fig. 2, and the non-conversion probabilities for \(\gamma\)'s and other particles, it is then possible to extract \(R\) for pure direct-photon events and pure neutral-meson events. The values obtained, shown in fig. 4 as a function of \(p_{T\text{trig}}\) for \(x_E > 0.3\), again exhibit the fact that \(R\) for single photons is higher than \(R\) for neutral mesons. It should be stressed that this difference in \(R\) between the two types of events is unaffected by the 20% systematic uncertainty in \(R\) described earlier. Note that direct-photon events arising from quark bremsstrahlung are excluded by the nature of the charge ratio analysis.

In conclusion, in this letter we have presented data that show that direct photons are produced predominantly

- with no additional particles in the trigger hemisphere,

- with a higher charge ratio than neutral mesons in the opposite hemisphere.

Both these results favour the process \(gq + \gamma q\) as the main source of the direct photons.
