We present a measurement of the mass difference between top (t) and anti-top (\bar{t}) quarks using \( t\bar{t} \) candidate events reconstructed in the final state with one lepton and multiple jets. We use the full data set of Tevatron \( \sqrt{s} = 1.96 \) TeV proton-antiproton collisions recorded by the CDF II detector, corresponding to an integrated luminosity of 8.7 fb\(^{-1}\). We estimate event-by-event the mass difference to construct templates for top pair signal events and background events. The resulting mass difference distribution in data compared to signal and background templates using a likelihood fit yields \( \Delta M_{\text{top}} = M_t - M_{\bar{t}} = -1.95 \pm 1.11 \) (stat) \( \pm 0.59 \) (syst) GeV/c\(^2\) and is in agreement with the standard model prediction of no mass difference.

PACS numbers: 14.65.Ha, 13.85.Ni, 13.85.Qk, 12.15.Ff

The laws of the standard model of particle physics (SM) are invariant under the simultaneous transformations of charge conjugation, parity, and time reversal (CPT). Conservation of CPT is, therefore, fundamental and provides one of the most important constraints on the SM. However, examining any possibility of CPT violation is important, as there are well-motivated extensions of the SM allowing for CPT symmetry breaking [1]. In CPT-conserving models, particles and their anti-particles must have identical masses and widths. Thus, any mass difference between a particle and its anti-particle would indicate a violation of CPT. CPT invariance has been tested for many elementary particles such as leptons and hadrons [2,3], but not in the bare quark except for the top quark [4]. For all quarks except the top quark, direct mass measurements of bare quark masses can be made.

Since the top quark discovery, close to three thousands of \( t\bar{t} \) candidate events have been collected per experiment at the Tevatron \( pp \) collider. This sample makes measuring the top-quark mass (\( M_{\text{top}} \)) possible to an accuracy of approximately 0.5% (\( M_{\text{top}} = 173.2 \pm 0.9 \) GeV/c\(^2\)) [5] and the mass difference (\( \Delta M_{\text{top}} = M_t - M_{\bar{t}} \)) between \( t \) and \( \bar{t} \) quarks to a comparable precision. The D0 collaboration performed several measurements of \( \Delta M_{\text{top}} \) using matrix element analyses [6,7]. The most recent D0 result, based on a 3.6 fb\(^{-1}\) data sample, reports \( \Delta M_{\text{top}} = 0.8 \pm 1.9 \) GeV/c\(^2\), consistent with zero as predicted in the SM. The CDF collaboration performed a measurement using a 5.6 fb\(^{-1}\) data sample [8] and found \( \Delta M_{\text{top}} = -3.3 \pm 1.7 \) GeV/c\(^2\) which is also consistent with zero to within two standard deviations. To date, the most precise measurement is performed by the CMS collaboration, \( \Delta M_{\text{top}} = -0.44 \pm 0.53 \) GeV/c\(^2\) [9].

This paper reports on the final CDF measurement of
\( \Delta M_{\text{top}} \) based on the full Run II data set corresponding to an integrated luminosity of 8.7 fb\(^{-1}\). We reconstruct the mass difference between \( t \) and \( \bar{t} \) quarks in each data event and compare its distribution with template distributions derived from Monte Carlo (MC) model simulations to estimate \( \Delta M_{\text{top}} \). This is an update of a previous measurement that used a subset of the present data [8]. In addition to the larger data sample, we improve the jet energy calibration by applying an artificial neural network to achieve better jet energy resolution [10], as in a recent measurement of \( M_{\text{top}} \) [11]. We also increase the size of the control samples and re-examine the systematic uncertainties.

In the SM, \( t \) and \( \bar{t} \) quarks decay almost exclusively into a \( W \) boson and a bottom quark (\( t \to bW^+ \) and \( \bar{t} \to bW^- \)) [12]. The case where one \( W \) boson decays to a charged lepton (electron or muon) and a neutrino (\( W^+ \to \ell^+ \nu \) or \( W^- \to \ell^- \bar{\nu} \) including the cascade decay of \( W \to \tau \nu \) and \( \tau \to \ell \nu \bar{\nu} \)) and the other to a pair of jets, defines the lepton+jets channel. To select \( t\bar{t} \) candidate events in this channel, we require one electron (muon) with \( E_T > 20 \text{ GeV} (p_T > 20 \text{ GeV}/c) \) and pseudorapidity \( |\eta| < 1.1 \) [13]. We also require large missing transverse energy \( \Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} = 0.4 \) [13]. Besides the standard jet energy scale corrections [16], we use an artificial neural network that includes additional information to the calorimeter one, such as jet momentum from the charged particles inside the jet [11]. This additional information improves the resolution on the reconstructed jet variables, resulting in approximately a 10\% improvement in statistical precision. Jets originating from \( b \) quarks are identified (tagged) using a secondary vertex tagging algorithm [17]. In order to optimize the background reduction and to improve the statistical power of the measurement, we divide the sample of \( t\bar{t} \) candidates into subsamples with zero (0-tag), one (1-tag), and two or more (2-tag) b-tagged jets.

For the 0-tag events, we require exactly four tight jets (transverse energy \( E_T > 20 \text{ GeV} \) and \( |\eta| < 2.0 \)). In case of the 1-tag and 2-tag events, three tight jets and one or more loose jets (\( E_T > 12 \text{ GeV} \) and \( |\eta| < 2.4 \)) are required. To reduce background contributions to the 0-tag events, we require the scalar sum of transverse energies in the event, \( H_T = E_T^{\text{lepton}} + E_T + \sum_{\text{four jets}} E_T^{\text{jet}} \), to exceed 250 GeV. The \( H_T \) requirement is not applied to the 2-tag events because of the small background contribution in this subsample. We divide the 1-tag and 2-tag samples into subsamples based on the number of tight jets. We denote as \textit{tight subsample} the sample requiring exactly four tight jets and \textit{loose subsample} the sample consisting of the remaining events. This results in five subsamples: 0-tag, 1-tagL, 1-tagT, 2-tagL, and 2-tagT, where L and T denote tight and loose subsamples, respectively.

The primary sources of background contributions are \( W \)+jets and QCD multijet processes. To estimate the contribution of each process, we use a combination of data- and MC-based techniques described in Ref. [18,19]. For the \( Z \)+jets, diboson, single top quark, and \( t\bar{t} \) events we normalize the number of simulated events using their theoretical cross sections [20,22]. We use the data-driven techniques described in Ref. [23] to estimate the QCD multijet background. The \( W \)+jets background shape is modeled using MC generated samples but the number of events is derived from the data sample by subtracting all other contributions, including the \( t\bar{t} \) signal, from the data events. Table 1 summarizes the data sample composition. The distribution of \( H_T \) is shown in Fig. 1 for data with 0-tag and one or more 2-tag (Tagged) with the predictions from our signal and background models.

We assume that all selected events are lepton+jets \( t\bar{t} \) events and reconstruct \( \Delta M_{\text{top}} \), event-by-event, using a special-purpose kinematic fitter [8]. Measured four-vectors of the lepton and jets are corrected for known effects as described in Ref. [16], and appropriate resolutions are assigned. The unclustered transverse energy \( (U_T) \) is estimated as a sum of all transverse energy in the calorimeters that is not associated with the primary lepton or with one of the leading four jets. It is used to calculate the neutrino transverse momentum. The longitudinal momentum of the neutrino is a free parameter which is effectively determined by the constraint on the invariant mass of the leptonically-decaying \( W \) boson. To estimate \( \Delta M_{\text{top}} \), we define a kinematic \( \chi^2 \) function,

\[
\chi^2 = \sum_{i=\ell} \sigma_{\text{jet}}^2 (p_T^{\text{fit}} - p_T^{\text{meas}})^2 / \sigma_i^2 + \sum_{k=x,y} (U_T^{\text{fit}} - U_T^{\text{meas}})^2 / \sigma_k^2
\]

\[
+ (M_{ij} - M_{W})^2 / \Gamma_W^2 + (M_{tW} - M_{W})^2 / \Gamma_W^2
\]

\[
+ \{M_{bW} - (M_{tW} + d_{\text{reco}}/2)\}^2 / \Gamma_t^2
\]

\[
+ \{M_{b\ell\nu} - (M_{tW} - d_{\text{reco}}/2)\}^2 / \Gamma_t^2,
\]

where \( d_{\text{reco}} \) is obtained at the lowest \( \chi^2 \) and represents the reconstructed mass difference between the hadronically- and leptonically-decaying top quarks, \( M_{bW} - M_{b\ell\nu} \). In Eq. (1), we constrain the lepton \( p_T \) and the four leading jets \( p_T \) to their measured values and uncertainties (\( \sigma_i \)). We also constrain \( U_T \) in the second term of Eq. (1). In the remaining terms, we constrain the \( W \) boson mass (\( M_W \)) to \( M_W = 80.4 \text{ GeV}/c^2 \) [23] and the average of \( t \) and \( \bar{t} \) masses to \( M_{tW} = 172.5 \text{ GeV}/c^2 \). The quantities \( M_{ij}, M_{bW}, M_{b\ell\nu}, \) and \( M_{b\ell\nu} \) refer to the invariant masses of the particles denoted in the subscripts. The total widths of the \( W \) boson, \( \Gamma_W = 2.1 \text{ GeV} \), and of the top quark, \( \Gamma_t = 1.5 \text{ GeV} \), are taken from Ref. [12]. We assume that the total widths of the \( t \) and \( \bar{t} \) quarks are equal. Determining the reconstructed mass difference of \( t \) and \( \bar{t} \), \( \Delta m_{t\bar{t}}^{\text{reco}} \), requires the identification of the particle type (\( t \) or \( \bar{t} \)), which is achieved using the electric charge of the lepton (\( Q_{\text{lepton}} \)), \( \Delta m_{t\bar{t}}^{\text{reco}} = -Q_{\text{lepton}} \cdot d_{\text{reco}} \). In the events with a positive (negative) lepton, \( t \) (\( \bar{t} \)) decays leptonically and \( \bar{t} \) (\( t \)) decays hadronically. Because of the different resolutions of the jets, lepton, and unclustered
TABLE I: Expected and observed numbers of signal and background events assuming a $t\bar{t}$ production cross section $\sigma_{t\bar{t}} = 7.45$ pb and $M_{top} = 172.5$ GeV/c$^2$.

Assuming that the leading four jets in any event come from the four final quarks of the $t\bar{t}$ lepton+jets decay at the hard scattering level, there are 12, 6, and 2 possible jet-to-quark assignments for 0-tag, 1-tag, and 2-tag samples, respectively. The $\chi^2$ minimization is performed for each jet-to-quark assignment, and $\Delta m_{t\bar{t}}^{reco}$ is taken from the assignment that yields the lowest $\chi^2$ ($\chi_{min}^2$). The $b$-tagged (zero $b$-tag) events with $\chi_{min}^2 > 9.0$ ($\chi_{min}^2 > 3.0$) are rejected due to the poorly reconstructed kinematical properties. To increase the statistical power of the measurement, we employ an additional observable, $\Delta m_t^{reco(2)}$, which corresponds to the 2nd lowest $\chi^2$ in the jet-to-quark combinatorics. Although it has a poorer sensitivity, $\Delta m_t^{reco(2)}$ provides additional information on $\Delta M_{top}$ and reduces the statistical uncertainty by approximately 10%. We use two observables ($\Delta m_t^{reco}$ and $\Delta m_t^{reco(2)}$) simultaneously for the measurement.

Using MADGRAPH [25], we generate $t\bar{t}$ signal samples with $\Delta M_{top}$ between $-20$ GeV/c$^2$ and 20 GeV/c$^2$ in 2 GeV/c$^2$ intervals. Parton showering of the signal events is simulated with PYTHIA [26], and the CDF II detector is simulated using a GEANT-based software package [27].

We estimate the probability density functions (PDFs) of signal and background using the kernel density estimation [28, 29]. We construct the two dimensional PDFs that account for the correlation between $\Delta m_t^{reco}$ and $\Delta m_t^{reco(2)}$. First, at discrete values of $\Delta M_{top}$ from $-20$ GeV/c$^2$ to 20 GeV/c$^2$, we estimate the PDFs for the observables from the above-mentioned MADGRAPH $t\bar{t}$ samples. We interpolate the MC distributions to find the PDFs for arbitrary values of $\Delta M_{top}$ using the local polynomial smoothing method [30]. Then, we fit the signal and background PDFs to the unbinned distributions observed in the data using a maximum likelihood fit [31]. Separate likelihoods are built for the ten subsamples, and the overall likelihood is obtained by multiplying them together. References [11, 28] provide detailed information about this technique.

We calibrate the method using the fully simulated MC experiments. We perform 3000 simulated experiments for

energy, the distribution of reconstructed mass from the hadronic top quark is different with that of the leptonic top quark. To improve the resolution of the $\Delta m_{t\bar{t}}^{reco}$, and allow using the appropriate distribution in the hadronic-to-leptonic and in the leptonic-to-hadronic mass difference, we divide each subsample into the two new subsamples based on the lepton charge. We then have ten subsamples in total.

Using MADGRAPH [25], we generate $t\bar{t}$ signal samples with $\Delta M_{top}$ between $-20$ GeV/c$^2$ and 20 GeV/c$^2$ in 2 GeV/c$^2$ intervals. Parton showering of the signal events is simulated with PYTHIA [26], and the CDF II detector is simulated using a GEANT-based software package [27].

Each of eleven equally-spaced $\Delta M_{\text{top}}$ values ranging from $-10$ GeV/$c^2$ to 10 GeV/$c^2$. The fit estimates and their uncertainties in the simulated experiments are found to be unbiased.

We examine a variety of systematic effects that could affect the $\Delta M_{\text{top}}$ measurement. To estimate the systematic uncertainties, we compare the results from simulated experiments in which we vary relevant parameters within one standard deviation. We estimate the systematic uncertainties in the assumptions of $M_{\text{top}} = 172.5$ GeV/$c^2$ and $\Delta M_{\text{top}} = 0.0$ GeV/$c^2$. All systematic uncertainties are summarized in Table II. The dominant source of systematic uncertainty is attributed to a possible difference in the detector response between $b$ and $\bar{b}$ jets. To estimate this effect, we select a $bb$ sample by requiring exactly two $b$-tagged jets per event using a sample triggered on jet ($E_T > 20$ GeV). In addition, one $b$-tagged jet is required to contain a soft muon from leptonic decay so that the charge tendency of the $b$ quark associated with the jet can be estimated. The energy scale of $b$ and $\bar{b}$ influenced jet events in data is compared with di-jet MC events in which we estimate the $p_T$ imbalance ($p_T$ of $b$ influenced jets minus $p_T$ of $\bar{b}$ influenced jets divided by average $p_T$) difference between the data and the MC events and obtain $-0.44 \pm 0.40\%$. To calculate the $p_T$ imbalance difference from $b$ and $\bar{b}$ jets, we estimate the fraction of the $b$ quark flavors associated with same charge of the soft muons. We obtain the $p_T$ imbalance difference to be $-0.73 \pm 0.67\%$ with considering incorrect charge events anti-correlatively. We perform simulated experiments by varying the $b$ and $\bar{b}$ energy within their $p_T$ imbalance difference. The possible difference of calorimeter responses between $c$ and $\bar{c}$ jets can be a source of systematic uncertainty. With an assumption of same asymmetry between $b$ and $\bar{b}$ jets as $c$ and $\bar{c}$ jets, we obtain a tiny uncertainty, 0.03 GeV/$c^2$, which is neglected. We estimate the signal modeling uncertainty by using simulated experiments with events generated with MADGRAPH and PYTHIA. We also estimate a parton showering uncertainty by applying different showering models (PYTHIA and HERWIG) to a sample generated with ALPGEN. Higher-order effects are estimated using MC@NLO generator. The background shape systematic uncertainty accounts for the variation of the background composition as well as the overall background fraction. We also consider changes in the shapes by varying the $Q^2$ used in the calculation of hard scattering and showering. The color reconnection systematic uncertainty is evaluated using the samples with and without color reconnection effects in PYTHA tunes. We use two samples with angular ordering for jet showers (tune A – Pro and tune ACR – Pro), same as the nominal samples of $\Delta M_{\text{top}}$ measurement. We also have a cross check using the other two samples with $p_T$ ordering for jet showers and new underlying-event model (Perugia0 and PerugiaNOCR) and find a similar uncertainty. We vary the parameters of parton distribution functions to account for systematic effects. The jet energy scale uncertainty, the dominant uncertainty in most of the $M_{\text{top}}$ measurements, is partially canceled in the $t$ and $\bar{t}$ mass difference. Other sources of systematic effects, including uncertainties in gluon radiation, multiple hadron interaction, finite size of MC samples, $b$-jet energy scale, and lepton energy scale, give small contributions. Because we assume the average $M_{\text{top}}$ to be 172.5 GeV/$c^2$, the $M_{\text{top}}$ dependence can be a possible source of systematic uncertainty. We perform the simulated experiments using different $t\bar{t}$ signal samples of $M_{\text{top}}$ from 170.0 GeV/$c^2$ to 175.0 GeV/$c^2$ with 0.5 GeV/$c^2$ steps. All samples have $\Delta M_{\text{top}} = 0$ GeV/$c^2$. We find the measured $\Delta M_{\text{top}}$ values, 0.01 $\pm$ 0.08 GeV/$c^2$ in the fit, are consistent with zero. The total systematic uncertainty of 0.59 GeV/$c^2$ is calculated as a quadrature sum of the listed uncertainties. The details of systematic uncertainty evaluations are in Ref [5,19,22].

The resulting mass difference is

$$\Delta M_{\text{top}} = -1.95 \pm 1.11 \text{ (stat)} \pm 0.59 \text{ (syst)} \text{ GeV/c}^2.$$  

Figure 2 shows the observed distributions of the observables used for the $\Delta M_{\text{top}}$ measurement. The density estimates for $t\bar{t}$ signal events with $\Delta M_{\text{top}} = 0$ GeV/$c^2$ and for background events are overlaid.

In conclusion, we examine the mass difference between $t$ and $\bar{t}$ quarks in the lepton+jets channel using CDF II data corresponding to an integrated luminosity of 8.7 fb$^{-1}$ from $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV. We measure the mass difference to be $\Delta M_{\text{top}} = M_t - M_{\bar{t}} = -1.95 \pm 1.11 \text{ (stat)} \pm 0.59 \text{ (syst)} \text{ GeV/c}^2 = -1.95 \pm 1.26 \text{ GeV/c}^2$. This result is consistent with $\Delta M_{\text{top}} = 0$ GeV/$c^2$ and conservation of CPT symmetry.
FIG. 2: Distributions of $\Delta m_1^{\text{reco}}$ and $\Delta m_1^{\text{reco}(2)}$ used to extract $\Delta M_{\text{top}}$ for zero $b$-tagged (0-tag) events and one or more $b$-tagged (Tagged) events. The data are overlaid with predictions from the kernel density estimation probability distributions assuming $\Delta M_{\text{top}} = 0$ GeV/$c^2$. The fitted number of signal and background events are used.

We thank the Fermilab staff and the technical staffs of the participating institutions for their vital contributions. This work was supported by the U.S. Department of Energy and National Science Foundation; the Italian Istituto Nazionale di Fisica Nucleare; the Ministry of Education, Culture, Sports, Science and Technology of Japan; the Natural Sciences and Engineering Research Council of Canada; the National Science Council of the Republic of China; the Swiss National Science Foundation; the A.P. Sloan Foundation; the Bundesministerium für Bildung und Forschung, Germany; the Korean World Class University Program, the National Research Foundation of Korea; the Science and Technology Facilities Council and the Royal Society, UK; the Russian Foundation for Basic Research; the Ministerio de Ciencia e Innovación, and Programa Consolider-Ingenio 2010, Spain; the Slovak R&D Agency; the Academy of Finland; and the Australian Research Council (ARC).

We use a right-handed spherical coordinate system with the origin at the center of the detector. $\theta$ and $\phi$ are the polar and azimuthal angles, respectively. The pseudo-rapidity is defined by $\eta = -\ln \tan(\theta/2)$. The transverse momentum and energy are defined by $p_T = p \sin(\theta)$ and $E_T = E \sin(\theta)$, respectively, where $p$ and $E$ are the momentum and energy of the particle.

The missing transverse energy, an imbalance of energy in the transverse plane of the detector, is defined by $\not{E}_T = -|\sum_{\text{towers}} E_T \hat{n}_T|$, where $\hat{n}_T$ is the unit vector normal to the beam and pointing to a given calorimeter tower and $E_T$ is the transverse energy measured in that tower.
