ABSTRACT

The yields of the atomic 4+3 transitions in antiprotonic $^{14}$N, $^{16,17,18}$O, $^{19}$F, and $^{23}$Na were measured at the CERN antiproton facility, LEAR. From these, the widths $\Gamma_{\text{up}}$ of the 4f levels were determined to be $136 \pm 19$ meV ($^{14}$N); $603 \pm 22$ meV ($^{16}$O); $731 \pm 35$ meV ($^{17}$O); $795 \pm 23$ meV ($^{18}$O); $2.79 \pm 0.16$ eV ($^{19}$F); and $23.8 \pm 7.4$ eV ($^{23}$Na).

1. **INTRODUCTION**

Exotic atoms are appropriate systems for the study of the strong-interaction potential between the antiproton and the nucleus at very low energies. The influence of the strong interaction shows up as a shift \( \varepsilon \) (difference between the measured energy and the calculated electromagnetic energy, \( \varepsilon = E_{\text{exp}} - E_{\text{em}} \)) of the atomic transition energies and as a broadening \( \Gamma \) of the atomic levels, measured by the line position and the line shape, respectively. Moreover, the absorption of the antiproton by the nucleus attenuates the atomic X-ray transitions. The shift and the width \( \Gamma_{\text{low}} \) of the lower level can be directly evaluated from the last observable atomic X-ray transition. The width \( \Gamma_{\text{up}} \) of the next higher level can be deduced from the intensity balance [1]. We have reported on our results for the (lower) 3d level \( (\varepsilon, \Gamma_{\text{low}}) \) of antiprotonic \( {}^{16,17,18}\text{O} \) in an earlier publication [2]. Here we report on the systematic study of the widths of the (upper) 4f level \( \Gamma_{\text{up}} \) for the antiprotonic \( {}^{14}\text{N}, {}^{16,17,18}\text{O}, {}^{19}\text{F}, \) and \( {}^{23}\text{Na} \) atoms.

2. **EXPERIMENT**

The experimental technique has already been described in some detail (ref. [2] and references therein). Here we will give only a short summary.

We measured the \( \bar{p} \)-atomic X-rays for several nuclei whose last observable atomic transition is the 4+3 at the M1 beam of the low-energy antiproton ring (LEAR) at CERN. The incident \( \bar{p} \) momenta were 300 MeV/c or 200 MeV/c. Sandwiched between two scintillation counters in coincidence, a polyethylene moderator slowed down the \( \bar{p} \)'s to be stopped in the target. We used a sodium fluoride crystal for the measurement on \( {}^{19}\text{F} \) and \( {}^{23}\text{Na} \) (5 spills \( \approx 647 \times 10^6 \) stopped \( \bar{p} \)); water in an aluminium frame with Be foils glued to it, for the oxygen isotopes \( {}^{16}\text{O} \) (4 spills \( \approx 296 \times 10^6 \) stopped \( \bar{p} \)), \( {}^{17}\text{O} \) (11 spills \( \approx 817 \times 10^6 \) stopped \( \bar{p} \)) and \( {}^{18}\text{O} \) (9 spills \( \approx 568 \times 10^6 \) stopped \( \bar{p} \)); and the contribution from stops in air (target \( {}^{6,7}\text{Li} \)) for \( {}^{14}\text{N} \) (4 spills \( \approx 680 \times 10^6 \) stopped \( \bar{p} \)). The FWHM of the range curves was of the order of 50 to 150 mg/cm², and thus smaller than the target thickness of 300 mg/cm². The average \( \bar{p} \) stop-rate was about \( 27 \times 10^3 \) s⁻¹ (\( 15 \times 10^3 \) s⁻¹) for 300 MeV/c (200 MeV/c) \( \bar{p} \) beam momentum. The X-rays were registered by four to six solid-state [Ge and Ge(Li)] detectors of various dimensions and energy ranges. The time of arrival and the energy of each event were stored on line in two-dimensional arrays in a MC68000 microprocessor memory. These arrays as well as the projected energy and time spectra were transferred to a PDP 11/34 computer for further data handling and evaluation.
3. DATA EVALUATION AND RESULTS

The energy calibration, energy resolution, and relative efficiency of each
detector were determined off line with radioactive sources and counter-checked
with those p-atomic X-ray lines which are not disturbed by strong-interaction
effects. The detection efficiency as a function of energy was determined by
fitting a semi-empirical formula for Ge(Li) detectors (eq. (8) in ref. [3]) to
the experimental data (fig. 1). The shapes of the efficiency curves determined
off beam were controlled under beam conditions and proved not to change under
beam load.

The spectra around the 4+3 region obtained with one of the detectors are
shown in fig. 2. The lines were fitted using standard procedures [2].

For each detector the measured intensities of the p lines were corrected
for efficiency and for target absorption. Table 1 shows the error-weighted means
(all detectors) of the corrected intensities, normalized to the 5+4 intensity.

The yield Y of the last X-ray transition (in this case 4+3) is given by

\[ Y(4+3) = P(4f) \frac{\Gamma_{\text{rad}}}{\Gamma_{\text{up}} + \Gamma_{\text{rad}} + \Gamma_{\text{Aug}}} \]  

(1)

where \( \Gamma_{\text{rad}}, \Gamma_{\text{Aug}}, \) and \( \Gamma_{\text{up}} \) are the radiation, the Auger, and the strong-
interaction widths of the 4f level, respectively, and P(4f) is its population.
If this level is fed only by X-ray transitions its population can be determined
from the intensities I of these X-rays:

\[ P(4f) = \sum_{n \geq 5} I(n \to 4) . \]  

(2)

Thus an upper width can be derived from the measured intensities by

\[ \Gamma_{\text{up}} = \Gamma_{\text{rad}} \left( \frac{\sum_{n \geq 5} I(n \to 4)}{I(4 \to 3)} - 1 \right) - \Gamma_{\text{Aug}} . \]  

(3)

The results of eq. (3) using the measured X-ray intensities are also given in
table 1; \( \Gamma_{\text{rad}} \) and \( \Gamma_{\text{Aug}} \) were taken from refs. [4] and [5]. The errors are purely
statistical.

The assumption of eq. (2) has to be verified for the following reasons:
a) The transitions n \to 4 have not been measured up to the series limit.
b) The measured intensities may still contain unresolved parallel transitions of
the type (n, l=3) \to (4, l=2), etc.
c) Radiationless Auger transitions may feed the 4f level.

Points (a) and (c) lead to an underestimate of P(4f) from eq. (2), whereas point
(b) leads to an overestimate. In order to resolve these problems, we have to
compare the measured intensity values with cascade calculations. For this we
use a code based on a cascade program written by Hübner [5], and described in
more detail in ref. [6]. The intensities of the X-ray transitions are calculated
by starting the atomic cascade at n = 40 and assuming a modified initial stat-
given there are the square roots of the quadratic sums of the changes in $\Gamma_{up}$ from $\alpha$ of the best fit to $\alpha' = \alpha \pm 0.01$, of the error arising from a similar treatment for $\Gamma_{up}^0 [\Gamma_{up}^0 = \Gamma_{up} \pm 10 \text{ meV} (100 \text{ meV for } ^23\text{Na})]$, and of our experimental error. The first one is of the order of 10-15 meV (135 meV for $^23\text{Na}$), the second of the order of 1 meV (7 meV for $^23\text{Na}$). Thus the leading contribution of the derived errors for $\Gamma_{up}$ is due to statistics.

The values for $\Gamma_{up}^*$ and $\Gamma_{up}$ agree quite well, indicating that the assumption of eq. (2) was justified within the accuracy of the experiment.

**4. DISCUSSION**

Figure 3 shows the strong-interaction widths $\Gamma_{up}$ for the $\bar{p}$-atomic 4f level as a function of the atomic weight for the various $\bar{p}$ atoms together with the results from our earlier measurement [8].

Our new values for $^{14}\text{N}$, $^{16}\text{O}$, and $^{18}\text{O}$ agree very well with the earlier ones, the errors being considerably smaller. The 4f width increases by $27\% \pm 2\%$ from $^{16}\text{O}$ to $^{18}\text{O}$, which is close to the isotope effect observed in the 3d level [2].

The data exhibit a clear A dependence, which is essentially described by the overlap of the $\bar{p}$-Coulomb wave function with the nucleus [$\Gamma = (Z\Lambda)^{1/3} - (Z\Lambda^{1/3})^9$]. The isotopes of oxygen clearly show different widths, but also here the effect can be described by the differences in the overlaps. This is demonstrated in fig. 4, where $\Gamma/(Z\Lambda^{1/3})^9$ is plotted versus $\Lambda$. The data points seem to be compatible with a constant: $\Gamma/(Z\Lambda^{1/3})^9 = (1.054 \pm 0.019) \times 10^{-12}$ [eV]. Hence, the effect in the upper level seems to be rather well handled by a perturbation calculation and justifies a posteriori the scaling applied in the cascade calculations eqs. (4) and (5). The influence of the factor $(1/1 + 1)^2$ in eq. 4 on the determined values for the upper level widths $\Gamma_{up}$ [eq. (6)] is of the order of 1% to 1%.

The width of the 4f level was calculated by several authors in refs. [9] to [12] on the basis of various potential models. Their values are also given in table 1 and fig. 3. Their results reproduce the general trend of our data rather well.

**Acknowledgements**

We would like to thank the LEAR staff for their collaboration during the data-taking of this experiment. For technical assistance we are grateful to H. Hagn, J. Hauth, E. Hecht, M. Meyer and P. Stoeckel. We also thank Dr. G. Büche for providing us with the electromagnetic transition energy calculations. The work was supported by the Bundesministerium für Forschung und Technologie of the Federal Republic of Germany, the Swiss National Science Foundation, and the US National Science Foundation.
