PHOTOPRODUCTION OF LARGE- p_T HADRONS
BY POLARIZED BEAM AND TARGET

Abstract: Production at large transverse momentum (p_T) of hadrons by a polarized photon beam on a longitudinally polarized proton target is studied. The contributions due to the structure of the photon are taken into account and discussed. In certain kinematic domains cross sections and event rates sizeable enough for successful experiments are predicted and single hadron production is shown to be a good probe of the size of the polarized gluon distribution. A particularly clean probe is found to be a special combination of cross sections for production of two large- p_T hadrons. The feasibility of high energy polarized photon beams is also discussed.

1. Introduction

So far the numerous tests of perturbative QCD (PQCD), which have led us to believe that it is a very successful theory of strong interactions, are experiments on reactions involving unpolarized partons and particles. One of these tests – quite successful – has been photoproduction of hadrons at large p_T .⁽¹⁾⁽²⁾ One may call the tests with unpolarized reactions first generation tests.

The EMC experiment on the longitudinally polarized structure function of the proton⁽³⁾ marks the beginning of a second generation of tests, perhaps more stringent than of the first. The results of this experiment are further enforced by the recent measurement of the spin-dependent structure function of the deuteron.⁽⁴⁾ Several other experiments with polarized particles have been completed⁽⁵⁾ or proposed at HERA⁽⁶⁾, RHIC⁽⁶⁾⁽⁷⁾ or Fermilab.⁽⁸⁾ One may expect that large p_T photoproduction of hadrons with polarized beam and target will eventually occupy a place.

The result of the EMC experiment was quite surprising: The valence quarks carry almost no spin of the proton! Within PQCD a solution was found in suggesting a large and positive polarized gluon distribution Δg (together with small polarized sea). An alternative solution consists of a rather large polarized strange sea together with a not so large Δg .

In this work we study the PQCD predictions for large- p_T photoproduction of hadrons by a polarized beam and proton target. In particular we present results with two sets of polarized parton distributions differing essentially in the size of Δg .

Section 2 presents the contributions to single hadron photoproduction of the main subprocesses. Sect. 3 presents the contributions due to the structure of the photon. Sect. 4 has our results on $\vec{\gamma}\vec{p} \rightarrow h + X$. Sect. 5 discusses two-hadron photoproduction and shows that a proper combination of cross sections for

$\bar{\gamma}\vec{p} \rightarrow h_1 + h_2 + X$ is, in principle, a clean probe of the size of Δg . Sect. 6 contains an overall assessment of the present work and our conclusions.

2. Single hadron photoproduction. _ Direct subprocesses.

We begin with photoproduction of a single hadron, namely $\bar{\gamma} + \vec{p} \rightarrow h + X$. In an important part of the kinematic range, this is known to be dominated by the subprocesses $\vec{g}\bar{\gamma} \rightarrow q\bar{q}$ and $\vec{q}\bar{\gamma} \rightarrow qg$ in which γ directly participates in the hard scattering process; of course, the coupling of the photon is point-like. Let $\vec{a}(p_1) + \bar{\gamma}(p_2) \rightarrow c(p_3) + d$ denote either of these (the quantities in parentheses are 4-momenta); we define:

$$\hat{s} = (p_1 + p_2)^2 \quad \hat{t} = (p_3 - p_1)^2 \quad \hat{u} = (p_3 - p_2)^2 \quad (2.1)$$

Next we write

$$\Delta \frac{d\sigma}{d\hat{t}} = \frac{1}{2} \left\{ \frac{d\sigma}{d\hat{t}}(a(+)\gamma(+) \rightarrow cd) - \frac{d\sigma}{d\hat{t}}(a(-)\gamma(+) \rightarrow cd) \right\} \quad (2.2)$$

where $\pm$ denote parton a and photon helicities. For the inclusive cross section of $\bar{\gamma}\vec{p} \rightarrow h + X$ we write likewise:

$$E \frac{\Delta d\sigma}{d^3p} = \frac{1}{2} \left\{ E \frac{d\sigma}{d^3p}(p(+)\gamma(+) \rightarrow hX) - E \frac{d\sigma}{d^3p}(p(-)\gamma(+) \rightarrow hX) \right\} \quad (2.3)$$

where $\pm$ denote proton and photon helicities. Then the contribution of $\vec{a}\bar{\gamma} \rightarrow cd$ is:

$$E \frac{\Delta d\sigma}{d^3p}(p_T, s, \eta) = \frac{1}{\pi} \sum_q e_q^2 \int \frac{dx_a}{x_a} \frac{dz}{z^2} \Delta F_{a/p}(x_a, Q^2) D_{h/c}(z, Q^2) \Delta \frac{d\sigma}{d\hat{t}} \delta(1 + \frac{\hat{t} + \hat{u}}{\hat{s}}) \quad (2.4)$$

where $\Delta F_{a/p}$ the momentum distribution of a longitudinally polarized parton a in the proton, $D_{h/c}$ the fragmentation function $c \rightarrow h$ and e_q denotes quark charge.

The subprocess cross sections are (see also Ref. 9):

$$\Delta \frac{d\sigma_{g\gamma}}{d\hat{t}} = -\frac{\pi\alpha\alpha_s}{\hat{s}^2} \frac{\hat{t}^2 + \hat{u}^2}{\hat{t}\hat{u}} \quad \Delta \frac{d\sigma_{q\gamma}}{d\hat{t}} = \frac{8\pi\alpha\alpha_s}{3\hat{s}^2} \frac{\hat{s}^2 - \hat{t}^2}{-\hat{s}\hat{t}} \quad (2.5)$$

where the outgoing antiquark (gluon) has momentum p_3 . With p_T the transverse momentum of h and η its c.m. rapidity with respect to the photon:

$$z = \frac{1}{2}x_T(e^\eta + e^{-\eta}/x_a) \quad (2.6)$$

where $x_T = 2p_T/\sqrt{s}$ ($\sqrt{s}$ = c.m. energy).

We are interested in photoproduction of charged hadrons (h^+, h^-). These are mostly π^+, π^- , to a lesser extent K^+, K^- and even less protons; production of $\bar{p}$ and other baryons is negligible. For π^+, π^- we use the fragmentation functions of Ref. 10 and note the relations:

$$D_{\pi^+/u} = D_{\pi^-/\bar{u}} = D_{\pi^-/d} = D_{\pi^+/\bar{d}} \quad D_{\pi^-/u} = D_{\pi^+/\bar{u}} = D_{\pi^+/d} = D_{\pi^-/\bar{d}} \quad (2.7)$$

and

$$D_{\pi^+/g} = D_{\pi^-/g} \quad (2.8)$$

Regarding fragmentation into $K^\pm$ we use the relations of Ref. 11

$$D_{K^+/u} = D_{K^-/\bar{u}} \quad D_{K^+/\bar{s}} = D_{K^-/s} \quad \frac{D_{K^-/u}}{D_{K^+/u}} = \frac{D_{\pi^-/u}}{D_{\pi^+/u}} \quad (2.9)$$

and

$$D_{K^+/s} = D_{K^+/d} = D_{K^+/\bar{d}} = D_{K^+/\bar{u}} = D_{K^-/\bar{s}} = D_{K^-/\bar{d}} = D_{K^-/d} = D_{K^-/u} \quad (2.10)$$

We take

$$D_{K^+/u} = D_{K^+/\bar{s}} = \frac{1}{3}D_{\pi^+/u}; \quad (2.11)$$

we find that at $Q^2 \simeq 4 \text{ GeV}^2$ the resulting $D_{K^+/u}(z, Q^2)$ and $D_{K^+/\bar{s}}(z, Q^2)$ are in fair agreement with the corresponding fragmentation functions of Ref. 11, as well as of Ref. 12. Finally we take $D_{K^\pm/g} = 0$ and neglect baryon production. In this way we find that photoproduction of all charged hadrons exceeds that of π^+ and

π^- by $\sim 40\%$ in agreement with well known experimental facts on large p_T hadron production.⁽¹³⁾

3. Photon structure (resolved photon) contributions.

In addition to the above direct subprocess, the photon may interact via two other mechanisms:⁽¹⁾⁽²⁾

- (i) Through its constituent $q\bar{q}$ pairs or gluons (partonic component); here, as in the direct subprocesses, the coupling of the photon is point-like.
- (ii) By first turning into a vector meson state (hadronic component) one may consider that this state is eventually decomposed into constituents, which give rise to some hard scattering subprocess.

Both mechanisms (i) and (ii) correspond to so called resolved photon subprocesses. We begin with (i).

With definitions similar to (2.1)–(2.3) and considering $\gamma \rightarrow q\bar{q}$, the contributions from $\bar{d}(p_1) + \bar{q}(p_2) \rightarrow c(p_3) + d(p_4)$ to the inclusive cross section of $\gamma\vec{p} \rightarrow h + X$ now has the form:

$$E \frac{\Delta d\sigma}{d^3p} = \frac{1}{\pi} \sum_q e_q^2 \int \frac{dx_a}{x_a} \frac{dx_b}{x_b} \frac{dz}{z^2} \Delta F_{a/p}(x_a, Q^2) \Delta F_{q/\gamma}(x_b, Q^2) D_{h/c}(z, Q^2) \times \\ \times \frac{\Delta d\sigma}{d\hat{t}}(aq \rightarrow cd) \delta\left(1 + \frac{\hat{t} + \hat{u}}{\hat{s}}\right) \quad (3.1)$$

Here $\Delta F_{q/\gamma}(x, Q^2)$ is the polarized photon structure function for $\gamma \rightarrow q$. For unpolarized photons there have been extensive studies regarding the structure function $F_{q/\gamma}$ (and $F_{g/\gamma}$); information on $\Delta F_{q/\gamma}$ (and $\Delta F_{g/\gamma}$) is much more limited. For the sake of simplicity and convenience we will make use of the lowest nontrivial order of α_s ; or quark parton model (QPM) result: as we discuss below, the matter is eventually related with the effects of the hadronic component (mechanism (ii)).

Thus we take:

$$\Delta F_{q/\gamma}(x, Q^2) = \frac{\alpha}{2\pi} \Delta P_{q/\gamma}(x) \log \frac{Q^2}{\tilde{\Lambda}^2} \quad (3.2)$$

where the polarized split function⁽¹⁴⁾

$$\Delta P_{q/\gamma}(x) = \frac{2x-1}{2}, \quad (3.2a)$$

and we take $\tilde{\Lambda} = \Lambda (= 0.2 \text{ GeV})$; to this order:

$$\Delta F_{g/\gamma}(x, Q^2) \equiv 0 \quad (3.3)$$

The subprocess cross sections $\frac{\Delta d\sigma}{d\hat{t}}(aq \rightarrow cd)$ have been determined in Ref. 9; with the notation

$$\frac{\Delta d\sigma}{d\hat{t}}(ab \rightarrow cd) = \frac{\pi \alpha_s^2}{\hat{s}^2} \Delta \Sigma(ab \rightarrow cd) \quad (3.4)$$

they are:

$$\Delta \Sigma(gq \rightarrow gq) = \frac{\hat{s}^2 - \hat{t}^2}{\hat{u}^2} + \frac{4}{9} \frac{\hat{s}^2 - \hat{t}^2}{-\hat{t}\hat{s}} \quad (3.5)$$

$$\Delta \Sigma(q_\alpha q_\beta \rightarrow q_\gamma q_\delta) = \frac{4}{9} \left(\frac{\hat{s}^2 - \hat{t}^2}{\hat{u}^2} + \delta_{\alpha\beta} \left(\frac{\hat{s}^2 - \hat{u}^2}{\hat{t}^2} - \frac{2}{3} \frac{\hat{s}^2}{\hat{t}\hat{u}} \right) \right) \quad (3.6)$$

$$\Delta \Sigma(q_\alpha \bar{q}_\beta \rightarrow q_\gamma \bar{q}_\delta) = \frac{4}{9} \left(\delta_{\alpha\gamma} \delta_{\beta\delta} \frac{\hat{s}^2 - \hat{t}^2}{\hat{u}^2} - \delta_{\alpha\beta} \delta_{\gamma\delta} \frac{\hat{t}^2 + \hat{u}^2}{3} - \frac{2}{3} \delta_{\alpha\gamma} \delta_{\beta\delta} \delta_{\gamma\delta} \frac{\hat{t}^2}{-\hat{u}\hat{s}} \right) \quad (3.7)$$

At the low end of p_T ($\lesssim 2.5 \text{ GeV}$) the Fermi motion (intrinsic transverse momentum of the partons in the hadron) has some effect. However, in photoproduction this effect is much less important than in hadron-hadron reactions, and it will be neglected.

Now we turn to the discussion of (3.2), (3.3) and begin by briefly recalling the situation in unpolarized γ reactions; we follow Refs. 15.

In the QPM $F_{q/\gamma}$ has the same form as (3.2) with only (3.2a) replaced by $P_{q/\gamma}(x)$; this is its simplest form, in which regularization-dependent constant (i.e. only x -dependent) pieces are neglected. Correspondingly $F_{g/\gamma}(x, Q^2) \equiv 0$, as well.

As for polarized γ , the result follows from the computation of a simple box graph. Inserted into the evolution equations, this contribution amounts to an inhomogeneous term. The full solution of these equations, to be termed leading order (LO) QCD, contains the homogeneous plus one particular inhomogeneous solution; the former is usually absorbed in the hadronic component. Then in the LO solution, $F_{q/\gamma}$ differs from that of QPM mainly near the kinematic endpoints $x = 0$ and $x = 1$. Of course, in LO, $F_{g/\gamma}(x, Q^2) \neq 0$.

In next-to-LO, for very large Q^2 (i.e. neglecting subdominant terms), $F_{q/\gamma}(x, Q^2)$ is given by the above inhomogeneous solution and is entirely calculable in QCD. This analysis was first made by Witten⁽¹⁶⁾ and led to the hope that the photon structure function could be fully predicted (i.e. including its x -dependence, apart from $\tilde{\Lambda}$ of Eq. (3.2)). Unfortunately the hope was shattered when it was realized that the singlet part of $F_{q/\gamma}$ contains a singularity at $x = 0$. In higher order this singularity becomes worse, and so are the indications for even higher orders; near $x = 0$, $F_{q/\gamma}$ even becomes negative! On the other hand, the full $F_{q/\gamma}$ is positive and regular; certain regularizing terms enter.⁽¹⁵⁾ The origin of them can be traced to the hadronic component (ii).⁽¹⁵⁾ Interesting ways to cancel the above singularities have been proposed,⁽¹⁷⁾ but the simplest (and perhaps safest) procedure seems the following:⁽¹⁸⁾ Accept $F_{q/\gamma}(x, Q_0^2)$ at some $Q_0^2 = \mathcal{O}(1 \text{ GeV}^2)$ from experiment (input) and use QCD to determine the evolution. This is the procedure one follows for partonic distributions in hadrons.

Now we turn to $\Delta F_{q/\gamma}$ and $\Delta F_{g/\gamma}$. In LO these functions have been determined.⁽¹⁹⁾ First, regarding $\Delta F_{q/\gamma}$, Fig. 1 of Ref. 19 shows that, away from kinematic endpoints, they are much the same as Eqs. (3.2). (3.2a) in sign, magnitude and structure (notice in all cases a change of sign of $\Delta F_{q/\gamma}(x, Q^2)$ at some intermediate x). Thus, away from $x = 0$ or 1, we may reasonably expect similar results.⁽²⁰⁾ Next,

regarding $\Delta F_{g/\gamma}$, Fig. 2 of Ref. 19 shows that it is important at small x . Setting $\Delta F_{g/\gamma} \equiv 0$ (eq. (3.3)), at larger x makes little difference.

In LO, at small x , all $\Delta F_{q/\gamma}, \Delta F_{g/\gamma}$ are $\sim x^{-1}$ (Ref. 19). For the next-to-LO nothing is known. Of course, no experimental input $\Delta F_{q/\gamma}(x, Q_0^2)$ is known, as well. Thus it appears to us that, away from $x = 0$ or 1, for simplicity's sake, use of (3.2) and (3.3) is not unjustified.

Furthermore, (3.2) and (3.3) are convenient to us, and this will be discussed in Sect. 5.

To close this section we note that, in contrast to the subprocesses $\bar{g}\bar{\gamma} \rightarrow q\bar{q}$ and $\bar{q}\bar{\gamma} \rightarrow qg$ which lead to events with 3-jet topology, the contributions due to the structure of the photon lead to 4 jets. The additional jet arises from the fragments of γ and emerges in the photon's direction. Thus such contributions can be eliminated by excluding 4-jet events. Anyway we present predictions both with and without these contributions.

4. Results on single hadron photoproduction.

Subsequently we use the two sets of polarized parton distributions of Ref. 21 (set 1: large Δg , set 2: relatively small Δg) evolved with Q^2 . In the running coupling $\alpha_s(Q^2)$ we take $\Lambda = 0.2$ GeV and four flavours. Our results correspond to the scale $Q^2 = p_T^2$, but we comment on other choices. We consider $\sqrt{s} = 27$ GeV and 170 GeV, but these energies should be viewed as only indicative.

Fig. 1 shows the contributions to $\bar{\gamma}\bar{p} \rightarrow \pi^\pm + X$ of the direct subprocesses, of the photon structure and of their sum for rapidities $\eta = 1.5, 0$ and -1.5 . The predictions correspond to set 1 of Ref. 21. In general the photon structure contributions are important at the lower p_T . The direct subprocesses dominate at $\eta = 1.5$ and $\eta = 0$, but not at $\eta = -1.5$.

Fig. 2 shows the ratio of the inclusive cross sections for $\vec{\gamma}\vec{p} \rightarrow \pi^\pm + X$ calculated with set 1 and set 2. In particular at $\eta = 1.5$ this ratio is near 2 and reflects the fact that at the indicated range of p_T the subprocesses with initial gluon dominate and that in set 1 $\Delta F_{g/p}$ is significantly larger than in set 2. It appears that in this kinematic range $\vec{\gamma}\vec{p} \rightarrow \pi^\pm + X$ is a good probe of the polarized gluon distribution.

Fig. 3 presents contributions of only the direct subprocesses to $\vec{\gamma}\vec{p} \rightarrow h^\pm + X$, where h denotes π or K . Following the NA14 collaboration⁽¹⁾ we present inclusive cross sections integrated over bins of p_T , namely

$$\Delta \frac{d^2\sigma}{d\eta d\phi}(p_T, s, \eta) = \int_{p_T - p_0}^{p_T + p_0} dp'_T p'_T E' \frac{\Delta d\sigma}{d^3p'}(p'_T, s, \eta) \quad (4.1)$$

For $\sqrt{s} = 27$ GeV we take $p_0 = 0.5$ GeV; for $\sqrt{s} = 170$: $p_0 = 1$ GeV. Again the predictions with set 1 exceed those of set 2 by factors ~ 2 .

For the direct subprocess contributions we also determine the asymmetries

$$A(p_T, s, \eta) = E \frac{\Delta d\sigma}{d^3p}(p_T, s, \eta) / E \frac{d\sigma}{d^3p}(p_T, s, \eta); \quad (4.2)$$

these are presented in Fig. 4. To determine the unpolarized $E d\sigma/d^3p$ we use the unpolarized parton distributions of Ref. 22 (fit SL-leading order). In general A are large and negative at the lower p_T . At fixed s , as p_T increases $|A|$ decreases; this is due to the fact that, with increasing p_T , the subprocess $\vec{q}\vec{\gamma} \rightarrow qg$ becomes relatively more important; this subprocess contributes with sign opposite to that of $\vec{g}\vec{\gamma} \rightarrow q\bar{q}$ (cf. Eqs. (2.5)). At even larger p_T (or x_T) $\vec{q}\vec{\gamma} \rightarrow qg$ dominates and A changes sign. Again, at the lower p_T , where $\vec{g}\vec{\gamma} \rightarrow q\bar{q}$ dominates, $|A|$ for solution 1 exceeds that for solution 2 by factors ~ 2 .

We have determined the event rates corresponding to our cross sections, and here we briefly state the main results. As a basis we take a differential luminosity of $15 \times 10^{30} \text{ cm}^{-2} \text{ sec}^{-1}$ (to be achieved later at HERA) and 1/3 of the year effective running time.

Referring to solution 1 and Eq. (4.1), we denote by N the per year number of events integrated over the bin $p_T - p_0 < p'_T < p_T + p_0$; we shall give the range of N for η varying in a range $\eta_{max} > \eta > \eta_{min}$. Then for solution 2, N can be trivially deduced from our Fig. 3.

So, for $\vec{\gamma}\vec{p} \rightarrow h^\pm + X$, at $\sqrt{s} = 27$ GeV, for the bin $2 < p'_T < 3$ GeV and for $1.5 > \eta > -1$ we find $4 \times 10^5 \gtrsim N \gtrsim 10^4$; in our kinematic range these correspond to the maximal rates. At $\sqrt{s} = 170$ GeV, for the bin $8 < p'_T < 10$ GeV and for $1.5 > \eta > -1.5$: $7 \times 10^3 \gtrsim N \gtrsim 20$; these correspond to the minimal rates. For $\gamma p \rightarrow h^\pm + X$ (unpolarized) approximate rates can be deduced from Fig. 4.

Leaving aside the technical difficulties in setting up polarized photon beams (see Sect. 6), it appears that, in general, our predicted cross sections and rates are sufficiently large for successful experiments.

Finally we have considered variations of the scale Q^2 in the usual range $p_T^2/4 \leq Q^2 \leq 4p_T^2$. Typically, for $Q^2 = p_T^2/4$ the polarized cross sections increase by factors of $2 \sim 2.5$ with respect to their value at $Q^2 = p_T^2$; for $Q^2 = 4p_T^2$, they decrease by factors $1.25 \sim 2$. In general, the asymmetries A are less affected: For the whole range $p_T^2/4 \leq Q^2 \leq 4p_T^2$ A changes by less than 20%.

5. Two-hadron photoproduction

As we stated in the Introduction, the size of Δg is a main issue in Spin Physics. Therefore it is of interest to isolate the subprocess $\vec{g}\vec{\gamma} \rightarrow q\bar{q}$. For this, as in Ref. 23, we consider the semi-inclusive production $\vec{\gamma}\vec{p} \rightarrow h_1 + h_2 + X$, where the hadrons $h_i, i = 1, 2$, are produced at large transverse momenta k_{T_i} in opposite azimuthal hemispheres.

To determine the contribution of the subprocess $\vec{a}\vec{\gamma} \rightarrow cd$, in the center of mass of the colliding γ and p take as z -axis the direction of $\gamma(\hat{z} = \hat{p}_2)$ and let θ_i and ϕ_i

the polar and azimuthal angles defining the direction of $\vec{k}_i$ (Fig. 5). We can take $\phi_1 = 0$, so that the plane defined by $\vec{p}_2$ and $\vec{k}_1$ (scattering plane) coincides with the $x - z$ plane. Then, with $k_{ix} = k_{Ti} \cos \phi_i$ and $\eta_i = \ell n \cot \frac{\theta_i}{2}$ the rapidity of h_i one obtains

$$\sigma(h_1 h_2) \equiv \frac{\Delta d\sigma}{d\eta_1 d^2 k_{T1} d\eta_2 dk_{2x}} = \frac{e_q^2}{\pi k_{T1}} \Delta F_{a/p}(x) \frac{\Delta d\sigma}{d\hat{t}} D_{h_1/c}(z_1) D_{h_2/d}(z_2), \quad (5.1)$$

where

$$x = e^{-\eta_1 - \eta_2} \quad (5.2)$$

and

$$z_1 = \frac{k_{T1}}{\sqrt{s}} (e^{\eta_1} + e^{\eta_2}) \quad z_2 = \frac{k_{2x}}{\sqrt{s}} (e^{\eta_1} + e^{\eta_2}). \quad (5.3)$$

In the above expression an integration over the component k_{2y} (perpendicular to the scattering plane) has been carried; also, in the expression of $\Delta d\sigma/d\hat{t}$ one has:

$$\hat{s} = xs \quad \hat{t} = -\hat{s}e^{\eta_1}/(e^{\eta_1} + e^{\eta_2}) \quad \hat{u} = -se^{-\eta_1}/(e^{\eta_1} + e^{\eta_2}) \quad (5.4)$$

Now using the relations (2.7) and (2.8) for the fragmentation functions to π^+ and π^- one can show that the combination of inclusive cross sections:

$$\Delta(\pi) \equiv \sigma(\pi^+ \pi^-) + \sigma(\pi^- \pi^+) - \sigma(\pi^+ \pi^+) - \sigma(\pi^- \pi^-) \quad (5.5)$$

isolates the contribution of the subprocess $\bar{\gamma}\vec{g} \rightarrow q\bar{q}$. One finds:⁽²³⁾

$$\Delta(\pi) = \frac{2(e_u^2 + e_d^2)}{\pi k_{T1}} \Delta F_{g/p}(x) \frac{\Delta d\sigma_{g\gamma}}{d\hat{t}} (D_{\pi^+/u}(z_1) - D_{\pi^-/u}(z_1))(D_{\pi^+/u}(z_2) - D_{\pi^-/u}(z_2)) \quad (5.6)$$

In a similar manner, using the relations (2.9) and (2.10) for the fragmentation functions to K^+ and K^- and assuming simply $D_{K^+/g} = D_{K^-/g}$, we find that the combination

$$\Delta(K) = \sigma(K^+ K^-) + \sigma(K^- K^+) - \sigma(K^+ K^+) - \sigma(K^- K^-) \quad (5.7)$$

isolates $\vec{\gamma}\vec{g} \rightarrow q\bar{q}$, as well. More specifically:

$$\Delta(K) = \frac{2}{\pi k_{T1}} \Delta F_{g/p}(x) \frac{\Delta d\sigma_{g\gamma}}{d\hat{t}} \sum_q e_q^2 \{ D_{K+/q}(z_1)(D_{K-/q}(z_2) - D_{K+/q}(z_2)) + D_{K-/q}(z_1)(D_{K-/q}(z_2) - D_{K+/q}(z_2)) \} \quad (5.8)$$

where $q = u, d$ and s .

Regarding the contributions of the photon structure, working as in Sect. 3 to the lowest nontrivial order of α_s (QPM) it is not difficult to demonstrate that in the combinations $\Delta(\pi)$ and $\Delta(K)$ these contributions cancel. The reason is that $\Delta(\pi)$ and $\Delta(K)$ involve differences of oppositely charged pions or kaons.

Moreover, since the inclusive cross section $\sigma(h_1 h_2)$ involves two hadrons in opposite hemispheres (Fig. 5) the effect of the Fermi motion is practically eliminated even at very low k_{Ti} . Thus (5.6) and (5.8) are very clean probes of the polarized gluon distribution $\Delta F_{g/p}$.

Now we can see the convenience (in addition to simplicity) in using the QPM $\Delta F_{q/\gamma}$ (Eq. (3.2)): It facilitates the demonstration that in the combinations $\Delta(\pi)$ and $\Delta(K)$ the photon structure contributions cancel. For the LO $\Delta F_{q/\gamma}^{(19)}$, the cancellation is not complete. However, in view of the many similarities between QPM and LO distributions discussed in Sect. 3 and away from kinematic endpoints, we may reasonably expect cancellation to a significant degree.

Fig. 6 presents results for the quantity $\Delta(\pi) + \Delta(K)$. The corresponding inclusive cross sections are integrated over bins of k_{T1} and k_{2x} , namely:

$$\frac{\Delta d\sigma}{d\eta_1 d\phi_1 d\eta_2}(k_{T1}, k_{2x}, s, \eta_1, \eta_2) = \int_{k_{T1}-k_0}^{k_{T1}+k_0} k'_{T1} dk'_{T1} \int_{k_{2x}-k_0}^{k_{2x}+k_0} dk'_{2x} \frac{\Delta d\sigma}{d\eta_1 d\eta_2 d^2 k'_{T1} dk'_{2x}} \quad (5.9)$$

We consider $\eta_1 = \eta_2 = \eta$ and as before take for $\sqrt{s} = 27$ GeV: $k_0 = 0.5$ GeV. for $\sqrt{s} = 170$ at the larger η , the cross sections show a clear difference (by factors ~ 2) between solutions 1 and 2.

We have again determined event rates on the basis of the luminosity and running time of Sect. 4. Referring to solution 1 and Eq. (5.9), we denote by N the per year number of events integrated over $k_{T1} - k_0 < k'_{T1} < k_{T1} + k_0$; with $\eta = \eta_1 = \eta_2$, for convenience, we give for $N = N(\eta)$ several characteristic values (although just one would be sufficient, the others being determined from our Fig. 6).

At $\sqrt{s} = 27$ GeV, the bin of k_{2x} is $2.5 < k'_{2x} < 3.5$ GeV (Fig. 6); then for the bin $2 < k'_{T1} < 3$ we find: $N(\eta = 1.5) \simeq 3.7 \times 10^3$, $N(\eta = 1.25) \simeq 10^4 (= N_{max})$ and $N(\eta = 0.55) \simeq 423$. At $\sqrt{s} = 170$ the bin of k_{2x} is $5 < k'_{2x} < 7$ (Fig. 6). Then for the bin $8 < k'_{T1} < 10$ we find: $N(\eta = 1.5) \simeq 210$, $N(\eta = 1) \simeq 19$ and $N(\eta = 0.55) \simeq 0.7$.

Leaving aside practical difficulties (see Sect. 6), we may say that, at the larger η , our predicted rates are not discouraging.

Before closing this section we would like to explain qualitatively the shapes of $\Delta d^3\sigma/d\eta_1 d\eta_2 d\phi_1$ and their difference between $\sqrt{s} = 27$ and $\sqrt{s} = 170$ GeV.

For $\sqrt{s} = 170$ GeV, with η varying in the range $0.5 < \eta < 1.5$, z_i are small (Eq. (5.3)) and the fragmentation functions $D_{h/q}(z_i)$ vary little, the behaviour of $\Delta(\pi)$ and $\Delta(K)$ is controlled by $\Delta F_{q/p}(x)$. Then as η increases, x decreases (Eq. (5.2)), and $\Delta F_{g/p}(x)$, which peaks at small x , increases. Hence $|\Delta d^3\sigma/d\eta_1 d\eta_2 d\phi_1|$ increases. Moreover, for the various bins of k_{T1} , this cross section almost scales.

For $\sqrt{s} = 27$ GeV, $k_{T1}/\sqrt{s}$ and $k_{2x}/\sqrt{s}$ are not so small, and this complicates the shape. First, at fixed k_{T1} and k_{2x} , beginning with $\eta = 0.5$ and up to some value of η , the behaviour of $\Delta(\pi)$ and $\Delta(K)$ is again controlled by $\Delta F_{g/p}(x)$; thus, as for $\sqrt{s} = 170$, $|\Delta d^3\sigma/d\eta_1 d\eta_2 d\phi_1|$ increases with η . At larger η , however, the variation of the fragmentation functions becomes important. As η further increases, z_1 and z_2 increase and $D_{h/q}(z_i)$ decrease fast, leading to a decrease of $|\Delta d^3\sigma/d\eta_1 d\eta_2 d\phi_1|$. Such a decrease results from another reason related with the fact that we integrate

over bins of k_{T1} and k_{2x} (Eq. (5.9)): For sufficiently large η , at $k'_{T1} = k_{T1} + k_0$ and/or $k'_{2x} = k_{2x} + k_0$ one has $z_1 > 1$ and/or $z_2 > 1$. Of course, in such kinematic ranges there can be no events, and in our calculation we have set $\Delta(\pi) = \Delta(K) = 0$.

6. Critical assessment and conclusions.

Now we discuss the feasibility of the foregoing experiments and the stability and reliability of our predictions against various uncertainties. We begin with the question of how one can obtain a high energy polarized photon beam.

Polarized photons (of squared 4-momentum $q^2 \simeq 0$) are produced from Bremsstrahlung (Brems) of polarized electrons deflected at very small angles. To determine the degree of photon polarization, in principle, one way is to tag the final electron (either by magnetic spectrometer or – better at high energy – by calorimetry methods) and determine the final electron's polarization by a double scattering experiment; all this is already quite hard. Moreover, in this way, the energy spectrum of the photons will have the usual Brems form, i.e. decreasing fast with photon energy E_γ . To produce a significant photon flux with high E_γ , one needs a very intense electron beam. Anyway, with degree of polarization $\sim 70\%$ of the initial electrons one anticipates a significant degree of photon polarization.

Perhaps a better way (presently developed at SLAC and discussed elsewhere⁽²⁴⁾) is via an optical laser beam. When the laser photons are backscattered on electrons, under proper arrangement, they can produce a spectrum peaked at some fairly high E_γ . The photons can be polarized and, in fact, with a large degree of polarization.

We turn to another question. In our predictions there are several uncertainties, and one may ask which of the observables is the most stable against (i.e. least affected by) these uncertainties. We argue that this is the asymmetry A , Eq. (4.2).

As we already discussed, regarding the choice of the scale Q^2 , A is more stable

than the individual cross sections; the reason is obvious.

Uncertainty is also involved in the fragmentation functions $D_{h/c}^{(25)}$. Again A is expected to be more stable since the same $D_{h/c}$ enter $E\Delta d\sigma/d^3p$ and $Ed\sigma/d^3p$. Changing $D_{h/c}$ will somewhat change our predicted rates, but not by order of magnitude.

An important uncertainty concerns higher order QCD corrections (HOC). Again A is expected to be more stable, and for this we argue as follows: For two different physical processes initiated by longitudinally polarized particles, namely $\tilde{\gamma}\tilde{p} \rightarrow \gamma$ (large- p_T) $+X$ and $\tilde{p}\tilde{p} \rightarrow \gamma$ (large- p_T) $+X$, complete next-to-leading order corrections have been determined.⁽²⁶⁾⁽²⁷⁾ For Drell-Yan lepton pair production by transversely polarized hadrons HOC have also been determined.⁽²⁸⁾ In all these cases it was found that the K -factors are much the same as of the corresponding unpolarized processes.⁽²⁹⁾⁽³⁰⁾ This is not accidental: As it is discussed and analyzed in Refs. 26, 27 and 28, it is due to the fact that, to a great extent, HOC for such processes are dominated by certain terms involving distributions; and that these terms are much the same in longitudinally polarized, transversely polarized and unpolarized processes. Then we may anticipate that the K -factors for $\tilde{\gamma}\tilde{p} \rightarrow h^\pm X$ and $\gamma p \rightarrow h^\pm X$ will not differ much.

Another question (not unrelated to the last one) is the reliability of our predictions. The discussion on $\Delta F_{q/\gamma}$ and $\Delta F_{g/\gamma}$ (Sect. 3) shows that at $x_T \equiv 2p_T/\sqrt{s} \sim 0$ (physically interesting region) and at $x_T \sim 1$ (less interesting since cross sections are small) our predictions are not very reliable. For not too small (and not too large) x_T , however, where the effects of photon structure are unimportant, we believe that solutions 1 and 2 reliably predict the anticipated range of cross sections.

Two hadron photoproduction (Sect. 5) is a way to bypass (to a great extent) various small- x uncertainties. Of course, the experiment is very difficult: In addi-

tion to the question of the feasibility of polarized photon beams, it demands the measurement of four cross sections; and to avoid large statistical errors, high statistics are required. Also, to avoid large systematic errors, all four cross sections must be measured in the same experiment. Thus the whole Sect. 5 may seem rather academic. Nevertheless, to our knowledge, the observables $\Delta(\pi)$ and $\Delta(K)$ are among the very few (the only ?) that isolate the polarized gluon distribution, Δg . Thus we believe they deserve our Sect. 5.

On the whole we may conclude that the processes of this paper are not to mark the beginning of determining Δg ; other processes, e.g. $\vec{p}\vec{p} \rightarrow \gamma$ (large- p_T) + $X^{(27)}$, are more appropriate. But as the understanding of importance of experiments with polarized particles (as second generation tests of QCD) and the development of polarization techniques progress, these processes may serve a useful purpose.

Acknowledgments

We would like to thank D. Hanna, A. Melissinos, C. Papanikolas and P. Patel for helpful discussions. One of us (APC) thanks X. Artru, G. Bunce, A. Efremov, G. Shapiro, O. Teryaev, R. Windmolders and other participants of the 5th International Workshop on H.E. Spin Physics ("Spin-93"), Protvino, Russia, 20-24 September 1993, as well as G. Jikia and other participants of the Joint Internat. Workshop, Zvenigorod, Russia, 15-21 September 1993, for many useful discussions. This work was also supported by the Natural Sciences and Engineering Research Council of Canada and by the Quebec Department of Education.

29. The same holds for Drell-Yan lepton pair production in longitudinally polarized hadron collisions.⁽³⁰⁾ This, however, follows trivially by the fact that emission of a (massless or massive) vector meson does not flip the helicity of a massless quark (helicity conservation); as a result, both Born term and 1-loop HOC for longitud. polarized Drell-Yan follow from the corresp. unpolarized by a simple change of sign. Note that, in general, with 1-loop HOC, parton distributions and fragmentation functions evolved via 2-loop anomalous dimensions and running coupling to 2-loop order, the sensitivity in e.g. the scale Q^2 is significantly reduced.
