Measurement of non-equilibrium carriers dynamics in Ce-doped YAG, LuAG and GAGG crystals with and without Mg-codoping

Abstract

Non-linear absorption spectroscopy in pump and probe configuration has been used to test the population of non-equilibrium carriers in Ce-doped Y$_3$Al$_5$O$_{12}$ (YAG), Lu$_3$Al$_5$O$_{12}$ (LuAG), and Gd$_3$Al$_x$Ga$_{5-x}$O$_{12}$ (GAGG) crystals with and without codoping by Mg$^{2+}$ ions. A faster rise time of the induced optical density has been observed in all crystals codoped with Mg with respect to that in Mg-free samples. A significant difference in the time evolution of the differential optical density in GAGG with respect to YAG and LuAG crystals has also been measured. In both GAGG:Ce and GAGG:Ce,Mg an absorption band with maximum in the blue-green range and a decay time of 1.4 ps is present. This band is due to the absorption by free electrons before they are trapped or re-captured by Ce$^{3+}$ ions. A broad absorption band in the yellow-red region with very short rise time and a decay time longer than 150 ps has been observed in all the Ce-doped garnets under study and can be attributed to the absorption from the Ce$^{3+}$ excited states.

Keywords: Scintillators, Multi-component garnet crystals, Non-linear absorption spectroscopy, Excitation transfer

1. Introduction

The rise time of the scintillation signal plays a crucial role in defining the time resolution achievable with a given scintillator, which depends on the interplay between the light yield and the kinetics of the scintillation process [1]. A shorter and brighter scintillation pulse leads to a smaller jitter on the arrival time of the first photons at the photo-detector. Therefore, these parameters are crucial in defining the potential application of inorganic scintillators for both time of flight positron emission tomography (TOF-PET) scans [2] and precision timing detectors in high energy physics experiments [3].

Recently, Ce-doped garnets with the chemical formula M$_3$A$_5$O$_{12}$, in which the metal M can be either a single yttrium / rare earth ion or their mixture; and the metal A can be Al, Ga or their mixture, have been extensively studied. Their main characteristics are high light yield, scintillation decay time shorter than 100 ns, and emission peaks around 540 nm, which can be exploited with the good sensitivity of silicon photo-multipliers (SiPM) at such wavelength.

The codoping of Ce-doped scintillation materials with alkali earth ions has been recently demonstrated to be a promising approach to improve the scintillation properties, especially in the scintillators with a garnet-type crystal matrix [4]. Such improvement is a combined result of the modification of electronic excitation transfer processes, achieved by band gap engineering, and the tailoring of the activator level energy within the gap, implemented via a variation of the garnet composition [5]. The codoping of the crystal using alkali earth ions results in the substitution of a trivalent ion in the host matrix with a divalent second-group cation and causes the formation of anionic vacancies that compensate the charge deficiency. The formation of a hole-type defect including Mg$^{2+}$ and O$^-$ in close proximity of the divalent cation is also favored [6]. Moreover, the codoping of Ce-activated crystals by divalent ions (even at the level of a few hundreds ppm) causes the oxidation of a fraction of the Ce$^{3+}$ ions into Ce$^{4+}$. Both these types of cerium ions are then involved in the scintillation process but with different kinetics [7]. The result is a significant accelera-
of the luminescence rise and decay times, as observed in Gd$_3$Al$_2$$_3$Ga$_2$$_7$O$_{12}$ (GAGG:Ce) crystals codoped with Mg [15]. This leads, as expected, to an improvement of the coincidence time resolution, as recently demonstrated for GAGG, Y$_3$Al$_5$O$_{12}$:Ce (YAG:Ce), and Lu$_3$Al$_5$O$_{12}$:Ce (LuAG:Ce) crystals [16, 17].

With respect to YAG and LuAG crystals, GAGG shows a peculiar feature: it contains numerous levels of $^7$F electronic states in the band gap, due to the presence of Gd$^{3+}$ ions. As recently shown in [15], the ground state $^8$S of Gd$^{3+}$ ions in GAGG crystals is located about 1 eV below the top of the valence band. A substantial difference in the excitation transfer to the radiating level of Ce$^{3+}$ in GAGG is thus expected with respect to Gd-free garnets. Since the luminescence build-up process is determined by the population of the Ce$^{3+}$ radiating levels, studying the time evolution of the population is a powerful tool to investigate both the luminescence response and the dynamics of free carriers before they are captured by traps and radiative centers. To study these processes, the population of the lowest excited levels can be probed by exploiting the optical pump-and-probe technique in which a femtosecond pulse pump is used for photo-excitation and a probe pulse of similar duration but with variable delay (with respect to the excitation pulse) is used to probe the free carrier density and the population of the excited electronic energy levels. In the current paper, a comparison of the fast excitation transfer processes in Ce-doped GAGG, YAG, and LuAG crystals, with and without Mg-codoping, is provided.

2. Experimental Methods

The six Ce-doped garnet samples used in this study were grown by Czochralski technique at a speed of about 1 mm/hour using an iridium crucible under N$_2$ atmosphere, or, in case of GAGG, under atmosphere of N$_2$ with 2% of O$_2$. For the GAGG samples, the seed crystal of (100) orientation was purchased from C&K Corporation, Sendai, Japan. Mixtures of oxides of purity 5N with compositions of Gd$_2$O$_3$, Ce$_2$O$_3$, Al$_2$O$_3$, Y$_2$O$_3$, and Lu$_2$O$_3$ powders was used as starting material. For the YAG and LuAG samples a stoichiometric mixture of 4N MgCO$_3$, CeO$_2$, a-Al$_2$O$_3$, Y$_2$O$_3$, and Lu$_2$O$_3$ powders was used as starting material. Namely, starting powders were prepared according to the formula of [Mg$_{50.005}$Ce$_{0.0005}$O$_{0.99}$Al$_{12}$O$_{12}$] and (Mg$_{50.005}$Ce$_{0.0005}$O$_{0.99}$)$_3$Al$_{12}$O$_{12}$ and seeds of (111) oriented YAG crystals were used. More details on the production method and the chemical compositions are described elsewhere [16, 17]. All the samples were cut from single crystal ingots in the shape of a $2 \times 2 \times 10$ mm$^3$ pixels and subsequently polished. The standard scintillation and optical properties of these samples were measured and discussed in [17].

The study of non-equilibrium carrier dynamics was performed using a pump-probe spectrometer based on an original femtosecond Ti:Al$_2$O$_3$ pulsed oscillator and a regenerative amplifier, both operating at 10 Hz repetition rate. A schematic diagram of the setup is shown in Fig. 1. The laser pulse duration and energy after amplification were 140 fs and up to 0.5 mJ, respectively, while the wavelength was tunable over the spectral range from 770 to 820 nm. The pulses of the fundamental frequency (the wavelength, $\lambda$, was set at 790 nm for the present study) were divided after the output of the amplifier into two parts at a ratio of 1:4. The beam of higher intensity was converted to the third harmonic ($\lambda \approx 263$ nm, pulse energy $E$ up to 12 $\mu$J) and used as the pump pulse. The pulse energy was selected low enough to prevent the sample surface from optical damage by the laser pulse. The second beam of smaller intensity was used as a probe.

After passing the delay line, the probe pulse was converted to a white super-continuum generated by focusing the beam into a 1 cm long water cell. By using a semi-transparent mirror, the super continuum radiation (360-800 nm) was subdivided into two pulses (reference and signal) of similar intensity. Both pulses were focused on the sample by mirror optics. The reference pulse was exploited to eliminate the impact of shot-to-shot instability of super-continuum. It passes the sample always before the pump pulse. The pump-induced change of the optical density was calculated as:

$$\Delta D(\lambda, \Delta t) = \log \left( \frac{E_{sg}(\lambda)}{E_{ref}(\lambda)} \right)$$

where $E_{sg}$, $E_{sg}^*$, and $E_{ref}$ are the energies of the signal pulses which passed the sample before and after the pump pulse, and the reference pulse, respectively. The beam spot diameter was 0.5 mm. The spectra of both pulses were recorded for each laser shot by a system including a polychromator equipped with a CCD camera and digitally processed. The absorption spectra of the white super continuum were measured in the spectral range from 400 to 700 nm. All measurements have been performed at room temperature. Additional details on the setup are provided in [19, 20, 21, 22], where the same technique and instrumental apparatus have been used for studies of ultrafast phenomena in different materials.
3. Results

The absorption spectra of the crystals under study, measured through 2 mm thickness using a Perkin Elmer (Lambda 650 UV/VIS) spectrometer, are shown in Fig. 2. All the Mg-free crystals exhibit the 4f-5d absorption bands corresponding to inter-configuration transitions of Ce$^{3+}$ ions. The samples codoped with Mg$^{2+}$ ions additionally show a broad absorption band in the UV region (below 300 nm). This band, related to the charge transfer (CT) transition from the valence band to a defect stabilized by Mg$^{2+}$ (e.g. Ce$^{4+}$ ions) [10], is more pronounced in the LuAG:Ce crystals having the lowest concentration of Ce$^{3+}$ ions. The absorption spectrum of the GAGG:Ce sample also shows a set of narrow absorption bands in the UV range corresponding to the transitions from $^8S$ ground state to the numerous components of P, I, and D terms split by spin-orbit interaction.

The transient induced absorption spectra of all samples for different delay times between the pump and the probe pulses are shown in Fig. 3. The pump wavelength, $\lambda_{ex} = 263$ nm, was chosen to avoid direct excitation of Gd$^{3+}$ states in GAGG crystals. For all the samples under study, such wavelength excites the Ce$^{3+}$ ions in the tail of the third component of the inter-configuration transition $4f^1$-5d$^1$4f$^0$ [23]. Since the corresponding excited level is located in the conduction band (CB), the de-localization of the non-equilibrium electrons and their capture might easily occur. In addition, the pump causes CT transitions in the defect centers due to the divalent ions introduced by the Mg-codoping. The differential optical density spectra of GAGG:Ce and YAG:Ce show a drop around 440-450 nm, in correspondence with the first $4f^1$-5d$^1$4f$^0$ allowed transition of Ce$^{3+}$ ions. This occurs due to a relatively larger concentration of Ce$^{3+}$ in these samples with respect to the lower dopant concentration in LuAG.

The spectra of GAGG:Ce samples contain two overlapping and wide absorption bands (local maxima in the spectrum): a first band, B1, having its maximum in the blue-green range (around 480 nm) and a second band, B2, peaking around 680 nm. As shown in the differential absorption kinetics, in Fig. 4 these bands appear simultaneously with the leading edge of the excitation. The B1 band (probed at 480 nm) shows an extremely fast decay component with time constant of $\tau_{d,1} = 1.4 \pm 0.2$ ps followed by another component with slower decay constant ($\sim 150$ ps). The time evolution of the B2 band intensity (probed at 680 nm) shows no fast component and decays with a comparably slow time constant as B1.

The B1 band is considerably less resolved in the absorption spectra of YAG:Ce and LuAG:Ce samples and no fast decay component in the kinetics is observed for the differential optical density probed at a spectral wavelength close to the B1 band (around 400 nm). The B2 band appears to have its maximum around 650 nm in YAG and LuAG samples and its slow decay time constant is also longer than in GAGG:Ce samples: it is about 400 ps for Mg-codoped LuAG and YAG and larger than 1000 ps for the respective Mg-free samples.

A comparison of the initial part of the differential optical density kinetics in LuAG:Ce, YAG:Ce and GAGG:Ce, with and without Mg-codoping, is better shown within a reduced time range in Fig. 5. The time evolution of the transient absorption in the Mg-codoped GAGG:Ce is similar to that in the sample without codoping, except for the fast component B1 which becomes faster and of smaller intensity. A faster rise time is also visible for LuAG:Ce and YAG:Ce Mg-codoped crystals with respect to the respective Mg-free samples and is further discussed in the following section.

4. Discussion

There is a significant difference between the defect formation process in YAG, LuAG and GAGG crystals. In garnet crystals containing two or more cations and isoivalent doping ions, e.g. Ce$^{3+}$ in our case, the defects are created...
ated by the preferential evaporation of the most volatile component from the melt during the crystal growth. In this case, randomly distributed vacancies will dominate. In GAGG crystals, where gallium is the most volatile component, the formation of cation vacancies due to the gallium evaporation inevitably leads to the formation of anionic vacancies and, consequently, to a higher concentration of trapping centers with respect to garnets grown from binary compositions. For example, oxygen vacancies create a set of electron trap levels with activation energy in the range up to 1 eV. Moreover, multicomponent garnet crystals favor the formation of additional defects that act as trapping centers for non-equilibrium carriers. The ratio of the ionic radii of Al and Ga is 0.39 Å to 0.47 Å in the oxygen tetrahedral positions and 0.53 Å to 0.62 Å in octahedral positions [24]. Therefore, even a random dis-
Figure 4: Time evolution of the probe differential absorption, $\Delta D$, at two different spectral regions of 400-480 and 650-680 nm for LuAG:Ce, YAG:Ce and GAGG:Ce single crystals (from top to bottom) with (left) and without (right) Mg-codoping.

The existence of a fast decay component in the transient absorption of GAGG:Ce samples was previously observed in [27]. The results presented in this work confirm its presence in GAGG:Ce and show that such component is absent in YAG:Ce and LuAG:Ce crystals, independently from the presence of Mg$^{2+}$ ions. This observation suggests that the transient absorption band peaking in the blue-green region, B1, cannot be associated with the excited radiating level of Ce$^{3+}$. Most probably, the B1 band is caused by free electron absorption, where the free electrons
Figure 5: Comparison of the early kinetics of the probe differential absorption, $\Delta D$, at two different spectral regions of 400-480 and 650-680 nm between Mg-codoped (dotted line) and Mg-free (solid line) samples of LuAG:Ce, YAG:Ce and GAGG:Ce single crystals (from top to bottom).

are generated via the absorption by Ce$^{3+}$ and the subsequent transfer of the electrons to the conduction band. The spectral width of the B1 band might be attributed to structured density of states in the conduction band [28].

The fast decay of the free electron absorption can be explained by the localization of free electrons at the traps in GAGG. Conversely, a maximum of the transient absorption around 650-680 nm (broad B2 band) is observed in all samples under study and could be attributed to the absorption from the Ce$^{3+}$ excited radiating levels.

This interpretation is also supported by the different kinetic behavior of the B1 and B2 absorption bands observed in the GAGG:Ce sample at the initial stage after the short-pulse excitation. The equilibrium between the free electrons and the electrons at the excited Ce$^{3+}$ level is established within approximately 2 ps after the pump excitation, while the further decay of both free electron density (probed at 480 nm) and the population of the excited Ce$^{3+}$ level (probed at 680 nm) proceeds at a similar rate, which is determined by radiative and non-radiative recombination processes. In the GAGG:Ce sample codoped with magnesium, the relative contribution of the fast component is smaller and its decay time faster ($\tau_d = 0.5 \pm 0.04$ ps) indicating that an additional recombination channel might have been introduced by codoping.

A difference in the rising time of the transient B2 absorption band kinetics between Mg-codoped and Mg-free garnets has also been observed as shown in Fig. 5. This difference is minimal in GAGG crystal but, in YAG and LuAG samples, the rising edge of the transient absorption response of the Mg-codoped crystals is considerably shorter due to capturing of free electrons from shallow traps. The Mg$^{2+}$-based defect centers, having a CT transition peaked at 265 nm, create deep trap levels approximately 1.5 eV below the bottom of conduction band. This can cause the same electrons to be captured multiple times from shallow traps and prevents them from being re-captured by Ce$^{3+}$ ions via the conduction band. Shallow traps capture electrons from the conduction band, while the thermal re-activation of the electrons back to the conduction band results in the population of Ce$^{3+}$ radiating levels and is responsible for the delayed luminescence observed in such samples. In Mg-codoped crystals, this process is substantially suppressed by the re-capturing of trapped electrons by Mg-related centers and thus the re-population from the traps is less probable. As a result, the transient absorption decay is faster in the codoped crystals. Meanwhile, the additional channel of non-radiative recombination, which is introduced by Mg-codoping, reduces the scintillation efficiency of garnet crystals.

5. Conclusions

The transient differential absorption of a set of Ce-doped $Y_3Al_5O_{12}$, Lu$_3Al_5O_{12}$ and Gd$_3Al_2Ga$_3$O$_{12}$ crystals with and without Mg-codoping has been measured by pump-probe method using femtosecond laser sources. The pump at the wavelength of 263 nm was used to create free carriers in all the samples under study, whereas white super-continuum was applied to measure transient absorption in the spectral range from 400 to 700 nm.

Substantial differences in the dynamics of population of the excited state of the activator ions in three garnet-type
scintillators: YAG:Ce, LuAG:Ce, and GAGG:Ce were revealed. Two non-linear absorption bands were observed. The first band, present in all three garnets, is broad and extends from approximately 450 nm over the whole visible region and decays with a characteristic time constant $\gtrsim 150$ ps. This band is attributed to the absorption from the lowest excited state of Ce$^{3+}$. The second band is peaked at the blue-green region, emerges in the sub-picosecond domain and has a decay time of $\sim 1.4$ ps. The time evolution of this band implies that it is caused by the light absorption by free electrons released to the conduction band after photo-excitation of Ce$^{3+}$ ions and rapidly captured by trapping states. This band is most pronounced in GAGG:Ce due to the influence of the second excited state of Ce$^{3+}$, which is in the conduction band close to its bottom, and is hardly traced in LuAG:Ce.

Pairs of samples of the crystals, nominally identical except of codoping by magnesium, were prepared to reveal the influence of codoping by divalent ions. We show that Mg-codoping introduces additional levels into the band gap, which facilitate transferring the trapped electrons back to the Ce ions.
