Abstract: I discuss two recent measurements by the ATLAS Collaboration [1] at the LHC on transverse energy-energy correlations and on the transverse momentum and rapidity dependence of dijet azimuthal decorrelations at $\sqrt{s} = 8$ TeV. They are based on the 2012 sample with an integrated luminosity of $20.2 \, fb^{-1}$. They are used to determine the strong coupling constant and to probe its running up to scales of order 2 TeV.

1 Measurement of transverse energy-energy correlations

Transverse energy-energy correlations (TEEC) are defined as the weighted average of azimuthal differences between jet pairs [2] i.e.:

$$
\frac{1}{\sigma} \frac{d\Sigma}{d(\cos \phi)} = \frac{1}{\sigma} \sum_{ij} \int \frac{d\sigma}{dx_{T1}dx_{T2}d(\cos \phi)} x_{T1}x_{T2}dx_{T1}dx_{T2},
$$

where the sum runs over all pairs of jets in the final state with azimuthal angular difference $\phi$ and $x_{T1} = \frac{E_{T1}}{E_T}$ is the transverse energy carried by jet $i$ in units of the sum of jet transverse energies $E_T = \sum_i E_{Ti}$.

In order to cancel uncertainties which are constant over $\cos \phi \in [-1,1]$, it is useful to define the azimuthal asymmetry of the TEEC (ATEEC) as

$$
\frac{1}{\sigma} \frac{d\Sigma^{\text{asym}}}{d(\cos \phi)} = \frac{1}{\sigma} \frac{d\Sigma}{d(\cos \phi)} \bigg|_{\phi} - \frac{1}{\sigma} \frac{d\Sigma}{d(\cos \phi)} \bigg|_{\pi-\phi}.
$$

Next to leading order (NLO) corrections have been recently calculated [3] using the NLOJET++ code [4]. They have been found to be moderate, with PDF uncertainties also well under control, thus making this observable suitable for a precise test of pQCD and for a determination of the strong coupling constant. Recent measurements of the TEEC have been published by the ATLAS Collaboration at 8 TeV [5]. The analysis represents an extension of previous measurements at 7 TeV [6]. The selection criteria require at least two anti-$k_T$ jets (R=0.4) such that $H_{T2} = p_{T1} + p_{T2} \geq 800 \, GeV$ with the transverse momenta of any additional jet above 100 GeV. To ensure that jet reconstruction is optimal, jets are required to be central with $|\eta_{\text{jet}}| \leq 2.5$. In the 2012 data sample used in this analysis the total number of selected events is $6.2 \times 10^6$. The data is further binned in six intervals in $H_{T2}$, the first one between 800-850 GeV and the last one above 1400 GeV. The data are corrected for detector effects using either a bin-by-bin correction or a Bayesian unfolding.

The systematic uncertainties are dominated by the choice of the MC model used in the unfolding, modelling, and by the jet energy scale, JES, which include 67 independent sources. The total systematic uncertainty for the TEEC measurements are always below the 4 – 5% level.

The unfolded data is fitted to NLOJET++ predictions which are dependent on $\alpha_s(M_Z)$. The choice of renormalization and factorization scales is $\mu_R = H_{T2}/2$ with $\mu_F = \mu_R/2$. The theoretical
uncertainties are dominated by the scale uncertainties, while those due to the PDF eigenvectors are subdominant.

The comparison between unfolded data for the TEEC (ATEEC) and theoretical predictions is fair as illustrated in Fig. 1 for the highest bin in $H_T^2$ namely $H_T^2 \geq 1400$ GeV.

Figure 1: Results of fitting the unfolded data on the TEEC (left) and its asymmetry (right) to NLOJET++ predictions [5].

The values for $\alpha_s$ obtained at scales $H_T/2$ from the TEEC and its asymmetry are shown in Fig. 2. They are in very good agreement with the renormalization group equation (RGE) dependence predicted in QCD. In fact, the goodness of this agreement has been used recently to put limits on new coloured fermions in a way which is independent of assumptions about their decay modes [7].

Figure 2: The scale dependence of $\alpha_s$ values obtained from TEEC (left) and ATEEC (right) measurements [5].

From a global fit to the complete data sample the following values for the strong coupling constant at the $Z$ boson mass are obtained:
• $\alpha_s^{TEEC}(M_Z) = 0.1162 \pm 0.0011 (\text{exp}) ^{+0.0076}_{-0.0061} (\text{scale}) \pm 0.0018 (PDF) \pm (0.0003) (NP)$

• $\alpha_s^{ATEC}(M_Z) = 0.1196 \pm 0.0013 (exp) ^{+0.0061}_{-0.0013} (scale) \pm 0.0017 (PDF) \pm (0.0004) (NP)$

## 2 Measurement of azimuthal decorrelations

The azimuthal decorrelations are defined [8] as the fraction of the inclusive dijet cross-section for which the azimuthal difference between the two leading jets is smaller than a given value, $\Delta \phi_{\text{max}}$:

$$R_{\Delta \phi}(H_T, y^*, \Delta \phi_{\text{max}}) = \frac{d^2\sigma_{\text{dijet}}(\Delta \phi_{\text{dijet}} < \Delta \phi_{\text{max}})}{dH_T dy^*} \frac{d^2\sigma_{\text{dijet}}(\text{inclusive})}{dH_T dy^*}$$  \hspace{1cm} (3)$$

ATLAS has recently presented measurements on azimuthal decorrelations [9] as an alternative method to determine the strong coupling constant and to probe pQCD at high scales. Anti-$k_T$ jets (R=0.6) are selected with $p_{T\text{min}} = 100$ GeV and $|y| \leq 2.5$. The selection criteria require $H_T = \sum_i p_{T_i} \geq 450$ GeV, $p_{T1} > H_T/3$, $y^* = |y_1 - y_2|/2 < 2$ and $|y_i - y_{\text{boost}}| < 0.5$ with $y_{\text{boost}} = (y_1 + y_2)/2$. The data are presented as a function of $H_T$ in three $y^*$ bins and four values of $\Delta \phi_{\text{max}}$.

The data are further corrected for detector effects using a bin-by-bin reweighting procedure. The systematic uncertainties are well under control, typically around the few percent level. The theoretical calculations have been performed as in the previous section using NLOJET++. The renormalization and factorization scales are set at $\mu_R = \mu_F = H_T/2$. The corrected data are shown in the left hand side of Fig. 3 along with a comparison to the NLO predictions.

![Figure 3](image-url)

Figure 3: The azimuthal decorrelations as a function of $H_T$ compared to NLO pQCD predictions [9], left. The values of $\alpha_s$ obtained from fits to $R_{\Delta \phi}$ for $\Delta \phi_{\text{max}} = 7\pi/8$, right.

The agreement is fair. A closer look at the data/theory ratios indicate that the predictions do best for $\Delta \phi_{\text{max}} = 7\pi/8$ as expected. Therefore for a determination of $\alpha_s$ the data for this particular
value of $\Delta \phi_{\text{max}}$ is integrated over $y^*$ and its $H_T$ dependence fitted to pQCD predictions at NLO accuracy. The results of this fit are shown on the right hand side of Fig. 3. They yield the following value for the strong coupling constant at the $Z$ mass: $\alpha_s^{\text{corr}}(M_Z) = 0.1127^{+0.0062}_{-0.0027}\text{(total)}$. The error is dominated again by the theoretical scale uncertainties.

3 Summary and conclusions

To summarize, two recent results on jet physics from the ATLAS Collaboration at the LHC have been discussed as ways to probe pQCD at high scales. The main quantitative result is that the coupling constant has been measured with good precision as illustrated in Fig. 4 and its running tested to unprecedented scales of the order of 2 TeV. In fact the level of experimental precision is similar to that of the LEP experiments. This calls for improved calculations beyond the NLO accuracy for three jet cross sections in $pp$ collisions [10].
