Abstract

As an extension of QCD, consider a theory with “2 + 1” flavors, where the current quark masses are held in a fixed ratio as the overall scale of the quark masses is varied. At nonzero temperature and baryon density it is expected that in the chiral limit the chiral phase transition is of first order. Increasing the quark mass from zero, the chiral transition becomes more weakly first order, and can end in a chiral critical point. We show that the only massless field at the chiral critical point is a sigma meson, with the universality class that of the Ising model. Present day lattice simulations indicate that QCD is (relatively) near to the chiral critical point.
Understanding the collisions of heavy ions at ultrarelativistic energies requires a detailed knowledge of the equilibrium phase diagram for QCD at nonzero temperature and baryon density. We generalize QCD to a non-abelian gauge theory with three colors and “2 + 1” flavors by holding the current quark masses in a fixed ratio as the overall mass scale is varied: $m \equiv m_{up} = m_{down} = r m_{strange}$, with $r$ a constant of order $\sim 1/20$. (For our purposes the difference between the up and down quark masses is inconsequential.) Currently, numerical simulations of lattice gauge theory [1] find that while there are lines of first order transitions coming up from $m = 0$ and down from $m = \infty$, these lines do not meet — there is a gap, with QCD somewhere in between. This is illustrated in fig. (1), following a similar diagram from the results of the Columbia group [2].

Lines of first order transitions typically end in critical points, so it is natural to ask about the two critical points, labeled “$C$” and “$D$” in fig. (1). As $m$ decreases from $m = \infty$, the line of deconfining first order phase transitions [3] can end in a deconfining critical point, “$D$” in fig. (1). Correlation functions between Polyakov lines are infinite ranged at the deconfining critical point; by an analysis similar to that in (II) below, one can show that $D$ lies in the universality class of the Ising model, or a $Z(2)$ spin system, in three dimensions.

The opposite limit is to work up from zero quark mass. For three flavors the chiral phase transition is expected to be of first order at $m = 0$ [4,5], so as $m$ increases, the line of first order transitions can end in a chiral critical point, “$C$” in fig. (1). In this Rapid Communication we show that for $2 + 1$ flavors there is only one massless field at the chiral critical point, a sigma meson ($J^P = 0^+$, predominantly isosinglet); the universality class is again that of the Ising model. Notice, however, that very different fields go critical at the two critical points $C$ and $D$.

I. We start at zero temperature by fitting the scalar and pseudoscalar mass spectrum in QCD to that found in a linear sigma model [4-6]. For three quark flavors we introduce the field $\Phi \sim \bar{q}_{left} q_{right}$, as a complex valued, three by three matrix, $\Phi = \sum_{a} (\sigma_{a} + i \pi_{a}) t^{a}$; $t^{a}_{1...8}$ are the generators of the $SU(3)$ algebra in the fundamental representation, and $t_{0}$ is proportional to the unit matrix. Normalizing the generators as $tr(t_a t_b) = \delta_{a,b}/2$, $t_0 = 1/\sqrt{6}$.

The fields $\sigma_{a}$ are components of a scalar ($J^P = 0^+$) nonet, those of $\pi_{a}$ a pseudoscalar ($J^P = 0^-$) nonet. The latter are familiar, as $\pi_{1,2,3}$ are the three pions, denoted as $\pi$ without subscript, and the $\pi_{4,5,6,7}$ are the four kaons, the
$K$’s. The $\pi_8$ and $\pi_0$ mix to form the mass eigenstates of the $\eta$ and $\eta'$ mesons, with mixing angle $\theta_{\eta\eta'}$ [7]. For notational ease we define the components of the scalar nonet analogously: we refer to $\sigma_{1,2,3}$ as the $\sigma_{\pi}$’s, to $\sigma_{4,5,6,7}$ as the $\sigma_K$’s, while $\sigma_8$ and $\sigma_0$ mix to form the $\sigma_\eta$ and $\sigma_{\eta'}$. This multiplicity of eighteen fields is to be contrasted with the usual sigma model with two flavors, which only has three $\pi$’s and one $\sigma$ meson.

The effective lagrangian for the $\Phi$ field is taken to be [4-6]

$$\mathcal{L} = tr \left[ \partial_{\mu} \Phi \right]^2 - tr \left( H(\Phi + \Phi^\dagger) \right) + \mu^2 tr \left( \Phi^\dagger \Phi \right)$$

(1)

$$- \sqrt{6} \; c \left( det(\Phi) + det(\Phi^\dagger) \right) + \left( g_1 - g_2 \right) \left( tr(\Phi^\dagger \Phi) \right)^2 + 3 g_2 \; tr \left( \Phi^\dagger \Phi \right)^2$$

The parameters of the linear sigma model are the background field $H$, a mass parameter $\mu^2$, an “instanton” coupling constant $c$, and two quartic couplings, $g_1$ and $g_2$. Neglecting effects from $m_{u_p} \neq m_{d_{down}}$, for the background field $H$ we take $H = h_0 t_0 - \sqrt{2} h_8 t_8$. The current quark masses are then related to the background field as $m_{u_p} = m_{d_{down}} \sim h_0 - h_8$ and $m_{strange} \sim h_0 + 2 h_8$.

Throughout this paper we work exclusively at the simplest level of mean field theory. Up to differences in normalization our intermediate results agree with those of Chan and Haymaker [6]. Because we attempt to fit to current experimental results [7], our fit in (2) differs from theirs; details will be presented elsewhere [8].

We assume that there are nonzero vacuum expectation values for $\sigma_0$ and $\sigma_8$, $\sigma_0 \rightarrow \Sigma_0 + \sigma_0$, $\sigma_8 \rightarrow -\sqrt{2} \Sigma_8 + \sigma_8$. Expanding the lagrangian in powers of $\sigma_8$ and $\pi_8$, expansion to linear order fixes the values of $\Sigma_0$ and $\Sigma_8$, while expansion to quadratic order gives the masses of all the fields: the mass of the pion, $m_\pi$, etc.

There is one unexpected feature of the results. For the two equations of motion, the masses of the entire pseudoscalar nonet (for $m_\pi$, $m_K$, $m_\eta$, and $m_\eta'$), and the masses of half the scalar nonet (for $m_{\sigma_\pi}$ and $m_{\sigma_K}$), the two quantities $\mu^2$ and $g_1$ only enter in tandem, through the new parameter $M^2 = \mu^2 + g_1 \left( \Sigma_0^2 + 2 \Sigma_8^2 \right)$. This means that we can fit to the pseudoscalar spectrum, and so fix $M^2$, and yet still be free to vary $g_1$: the only change is to alter the masses of the $\sigma_\eta$ and the $\sigma_{\eta'}$. This technical detail plays an important role in what follows; although there must be some simple group theoretic reason for it, as of yet we do not know what it is.

We determine the parameters of the linear sigma model by fitting to $m_\pi = 137 \; MeV$, $m_\eta = 547 \; MeV$, and $m_{\eta'} = 958 \; MeV$, and to the pion decay
constant, \( f_\pi = 93\ MeV \). A solution is

\[
\Sigma_0 = 127\ MeV \ , \ \Sigma_8 = 13\ MeV \ , \ h_0 = (290\ MeV)^3 \ , \ h_8 = (281\ MeV)^3 \ ,
\]

\[
M^2 = + (642\ MeV)^2 \ , \ c = 1920\ MeV \ , \ g_2 = 30 .
\]

(2)

Following [6], these values were obtained by varying \( \Sigma_8/\Sigma_0 \) as a free parameter. This is possible because the kaon mass is rather insensitive to \( \Sigma_8/\Sigma_0 \); for (2) the kaon mass is a bit high, \( m_K^{fit} = 516\ MeV \) instead of the (average) experimental value of 497\ MeV. Other quantities, however, are most sensitive to \( \Sigma_8/\Sigma_0 \); in particular, the kaon decay constant favors a small ratio, as \( f_K^{fit} = 109\ MeV \) is close to the experimental value of 113\ MeV. Also, the \( \eta-\eta' \) mixing angle, \( \theta_{\eta\eta'}^{fit} = -10.4^\circ \), is reasonable. (The value obtained from radiative decays [9], \( \theta_{\eta\eta'}^{rad} = -20^\circ \), favors even smaller values of \( \Sigma_8/\Sigma_0 \).) Further, because \( \Sigma_8 \neq 0 \), the ratio of the strange to up (or down) quark masses is \( m_{strange}/m_{up} = (h_0 + 2h_8)/(h_0 - h_8) = 32 \), and not the often quoted value of \( \sim 20 \).

The fit makes unique predictions for two masses in the scalar nonet, \( m_{\sigma_\pi} = 1177\ MeV \) and \( m_{\sigma_K} = 1322\ MeV \). There are observed states [7] with these quantum numbers, the \( a_0(980) \) and the \( K_0^*(1430) \), respectively; the values for the \( \sigma_\pi \) and the \( \sigma_K \) aren’t too far off, although the splitting between them is too small. We note that the identification of the \( a_0 \) with the \( \sigma_\pi \) is problematic (VII.21 of ref. [7]): the \( a_0(980) \) may not be the \( \sigma_\pi \) [10], but a \( K\overline{K} \) molecule [11].

There is no unique prediction for two other members of the scalar nonet, the \( \sigma_\eta \) and the \( \sigma_{\eta'} \). As remarked, the masses of all other fields only depends upon the parameter \( M^2 \). In fig. (2) we illustrate how \( m_{\sigma_\eta} \) and \( m_{\sigma_{\eta'}} \) change as \( g_1 \) is varied at fixed \( M^2 = +(642\ MeV)^2 \). We identify the \( \sigma_{\eta'} \) and the \( \sigma_\eta \) with the observed states [7] with the same quantum numbers: the \( f_0(975) \) and the \( f_0(1400) \), respectively. With the parameters of (2), if we require that \( m_{\sigma_{\eta'}} = 975\ MeV \), fig. (2) predicts that \( m_{\sigma_\eta} = 1476\ MeV \) instead of \( 1400\ MeV \). Also, \( g_1 = 40, \mu^2 = -(492\ MeV)^2 \), and the mixing angle between the \( \sigma_\eta \) and the \( \sigma_{\eta'} \) is \( +28^\circ \). As before the identification of the \( \sigma_{\eta'} \) with the \( f_0(975) \) is open to question (VII.192 of ref. [7]): the \( f_0(975) \) may be not the \( \sigma_{\eta'} \) [12], but a \( K\overline{K} \) molecule [11]. For the analysis of (III), all that is important is that the \( \sigma_{\eta'} \) is not light [13], so at zero temperature the quartic coupling \( g_1 \) is large.
II. The details of the spectrum at zero temperature are not needed to understand how a chiral critical point can arise. In mean field theory the effects of nonzero temperature or baryon density are incorporated simply by varying the mass parameter $\mu^2$. This is valid in the limit of very high temperature, but should be qualitatively correct at all temperatures.

We begin with the $SU(3)$ symmetric case, $h_8 = 0$. For a constant field $\Sigma_0$ the lagrangian reduces to the potential for $\Sigma_0$,

$$\mathcal{L} = -h_0 \Sigma_0 + \frac{1}{2} \mu^2 \Sigma_0^2 - \frac{c}{3} \Sigma_0^3 + \frac{g_1}{4} \Sigma_0^4. \quad (3)$$

This model has precisely the same phase diagram as that for the phase transition between a liquid and a gas. For zero background field, $h_0 = 0$, the instanton interaction $\text{det}(\Phi) \sim \Sigma_0^3$ is cubic and so drives the transition first order. As $h_0$ increases the transition becomes more weakly first order, until at $h_0 = h_0^{\text{crit}}$ the line of first order transitions ends in a critical point. For $h_0 > h_0^{\text{crit}}$ there is no true phase transition, just a smooth crossover.

The critical point occurs when $h_0^{\text{crit}} = c^3/(27g_1^2)$, $\Sigma_0^{\text{crit}} = c/(2g_1)$, and $\mu^2 = c^2/(3g_1)$. At this point the potential in $\Sigma_0 - \Sigma_0^{\text{crit}}$ is purely quartic, $\mathcal{L} = g_1(\Sigma_0 - \Sigma_0^{\text{crit}})^4/4$, so $m_{\sigma_{\eta'}} = 0$. The other fields are all massive: $m_{\sigma_{\eta'}} = m_K = m_{\sigma'}^2 = c^2/(9g_1)$, $m_{\sigma_{\eta'}}^2 = 10m_{\sigma'}^2$, $m_{\sigma_{\eta'}}^2 = m_{\sigma_K}^2 = m_{\sigma_{\eta'}}^2 = (7 + 18g_2/g_1)m_{\sigma'}^2$. Since only the $\sigma_{\eta'}$ is massless at the chiral critical point, the similarity to the liquid gas phase transition extends to the universality class, which is that of the Ising model.

This conclusion remains true away from the case of $SU(3)$ symmetry, $h_8 \neq 0$. Numerical analysis [8] shows that there is a single, massless field at the chiral critical point, the $\sigma_{\eta'}$, with the universality class that of the Ising model. Of course for $h_8 \neq 0$ the $\sigma_{\eta'}$ field does not remain a pure $SU(3)$ singlet, but mixes to become part octet.

The possibility of a chiral critical point can even be seen from the calculation of the zero temperature spectrum in fig. (2). Although we did not remark upon it before, when the coupling $g_1 \sim 3.8$, $m_{\sigma_{\eta'}} = 0$. There it appears as mere curiosity; after all, in fig. (2) $\mu^2$ has the value appropriate to zero temperature, while the value of $\mu^2$ at nonzero temperature (or baryon density) must be larger. Even so, fig. (2) does illustrate how a single field, the $\sigma_{\eta'}$, can become massless at a special point in the phase diagram.

We can further explain the nature of the entire phase diagram as a function of $m_{\text{up}} = m_{\text{down}}$ versus $m_{\text{strange}}$, as proposed in fig. (1) of ref. [2]. The
The basic idea is along the entire line of chiral critical points, only the $\sigma_\eta'$ is massless, but that the singlet/octet ratio in the $\sigma_\eta'$ changes. At the $SU(3)$ symmetric point, $m_{up} = m_{down} = m_{\text{strange}}$, the $\sigma_\eta'$ is an $SU(3)$ singlet. Decreasing $m_{\text{strange}}$ to the critical point where $m_{\text{strange}} = 0$ and $m_{up} = m_{down} \neq 0$, the $\sigma_\eta'$ becomes entirely strange, $\sigma_\eta' \sim \frac{s}{2}$.

The opposite limit of $SU(2)$ chiral symmetry, $m_{up} = m_{down} = 0$, is more familiar. Assume, as in ref. [2], that the chiral phase transition with two massless flavors is of second order, with the universality class that of an $O(4)$ critical point. There is then a special value of $m_{\text{strange}} = m_{\text{crit}}$, with a line of $O(4)$ critical points for $m_{\text{strange}} > m_{\text{crit}}$, and a line of first order transitions when $m_{\text{strange}} < m_{\text{crit}}$. Wilczek [14] observed that exactly at $m_{\text{strange}} = m_{\text{crit}}$, the chiral transition is in the universality class of an $O(4)$ tricritical point. In our view, at the critical points along $m_{\text{strange}} \geq m_{\text{crit}}$, the $\sigma_\eta'$ is a pure $SU(2)$ state, with $\sigma_\eta' \sim \bar{u}u + \bar{d}d$, while the pions are massless because $m_{up} = m_{down} = 0$. Whether the universality class is $O(4)$ critical or $O(4)$ tricritical depends upon the relevant quartic couplings.

The analysis can be extended to the case where the chiral transition is of first order for two, massless flavors, but the gap between chiral and deconfining regions remains. Then fig. (1) of ref. [2] would have to be modified, with a band of first order transitions about the axis $m_{up} = m_{down} = 0$. These first order transitions would end in chiral critical points, in the Ising universality class from the presence of massless $\sigma_\eta'$ fields.

III. Lastly we ask: How far is QCD from the chiral critical point? In fig. (1) we have grossly exaggerated the case, putting QCD very close to the chiral critical point. But the data of ref. [2] does indicate that as a function of $m$, QCD is only about a factor of two from the chiral critical point.

We first assume that the chiral phase transition is of first order for three, massless flavors because of the presence of the instanton coupling $\sim det(\Phi)$. To find the chiral critical point we vary the current quark masses, or equivalently the background fields $h_0$ and $h_8$. We require that the ratio of strange to up quark masses equals the value found from the fit at zero temperature, $(h_0 + 2h_8)/(h_0 - h_8) = 32$. By varying $h_0$, $h_8$, $\mu^2$, $\Sigma_0$, and $\Sigma_8$, and otherwise using the values found in (2) we find that the critical point occurs for $h_0^{\text{crit}} = (62 \text{ MeV})^3$, $h_8^{\text{crit}} = (60.4 \text{ MeV})^3$, $\mu^2_{\text{crit}} = (183 \text{ MeV})^2$, $\Sigma_0^{\text{crit}} = 14.5 \text{ MeV}$, and $\Sigma_8^{\text{crit}} = 2.7 \text{ MeV}$. We then compute the ratio be-
tween the current quark masses at the chiral critical point to those in $QCD$:

$$\frac{m_{\sigma_{\text{crit}}}^{\mu p}}{m_{\mu p}} = \frac{h_0^{\sigma_{\text{crit}}}}{h_0} - \frac{h_8^{\sigma_{\text{crit}}}}{h_8} = .01 \ .$$

(4)

Now we readily confess that this ratio, computed in mean field theory, is at
best crude. Even so, numerical simulations [2] find that the ratio in (4) is not
.01, but $\sim .5$ — mean field theory is off by almost two orders of magnitude!

Thus our initial assumption must be false. In the chiral limit for three
flavors, there are two mechanisms for generating a first order transition. The
first is the presence of the instanton coupling $\sim det(\Phi)$ [4,5]. From (4) this
gives the wrong phase diagram. Therefore the second mechanism must be
operative, a type of Coleman-Weinberg transition [15].

In mean field theory quartic couplings are fixed and do not change with
temperature; a Coleman-Weinberg transition is one in which the quartic
couplings run from a stable into an unstable regime, and so thereby generate a
finite correlation length dynamically. This phenomenon can be demonstrated
rigorously in 4 and 4 $-$ $\epsilon$ dimensions [15-18]; extrapolation to three dimensions,
$\epsilon = 1$, is open to question.

If in the chiral limit the phase transition is of first order because it is
Coleman-Weinberg, it is reasonable to suggest that even for nonzero quark
mass the quartic couplings change significantly with temperature. Since
$QCD$ appears to be in a region of smooth crossover, presumably the quartic
couplings of the sigma model do not run all the way into the unstable regime.
This could explain the apparent discrepancy with mean field theory in (4).
At the very least the quartic couplings do tend to run in the right direction:
in the infrared limit in less than four dimensions [17,18], the couplings run
most strongly for large $g_2$, approximately at constant $g_2$ from large to small
values of $g_1$. This type of running is precisely what is required at the chiral
critical point: as illustrated in fig. (2), even at zero temperature we can make
$\sigma_{\eta'}$ massless by going from large to small values of $g_1$, keeping $g_2$ fixed.

Given the limitations inherent in present lattice simulations for 2 $+$ 1
flavors, we conclude with a conjecture: as suggested by our illustration in fig.
(2), perhaps $QCD$ is very close to the chiral critical point. There is no good
reason why it should be; but if we are lucky, then even if there is no true phase
transition in $QCD$, the $\sigma_{\eta'}$ could still become very light. As we alluded to
previously [19], a light $\sigma_{\eta'}$ may generate large domains of Disoriented Chiral
Condenstates in the collisions of large nuclei at ultrarelativistic energies [8].

6
Speculation aside, we have shown how a detailed understanding of the spectrum of the scalar nonet at zero temperature — especially knowing exactly where the $\sigma_v$ meson lies — has direct and dramatic consequences for the phase diagram of $QCD$ at nonzero temperature and baryon density. In this way, one area of hadronic physics unexpectedly fertilizes another.

R.D.P. thanks Carl Dover, Yue Shen, and Edward Shuryak for discussions. This work was supported by a DOE grant at Brookhaven National Laboratory (DE-AC02-76CH00016) and by a National Science Foundation grant at the Institute for Theoretical Physics (PHY89-04035).

References

[13] We recognize that models of nucleon-nucleon forces do postulate the existence of a $\sigma$ meson with a mass of $\sim 600\,MeV$. It is reasonable to view this $\sigma$ meson as an approximation to two pion exchange; there is no such resonance seen in the phase shifts of $\pi - \pi$ scattering below $1\,GeV$, VII.37 of ref. [7]. For the purposes of discussion, we note that if we take $m_{\sigma'} = 600\,MeV$, the coupling $g_1$ decreases to $g_1 = 16.2$, while $m_{\sigma_n} = 1412\,MeV$ and $\mu^2 = +(384\,MeV)^2$. The ratio in (4) goes up, from .01 to .06, which is still a long way from $\sim .5$, ref. [2].
