Effective field theory approach to parton-hadron conversion
in high energy QCD processes

(Received 15 September 1994)

A QCD-based effective action is constructed to describe the dynamics of confinement and symmetry breaking in the process of parton-hadron conversion. The deconfined quark and gluon degrees of freedom of the perturbative QCD vacuum are coupled to color singlet collective fields representing the nonperturbative vacuum with broken scale and chiral symmetry. The effective action recovers QCD with its scale and chiral symmetry properties at short space-time distances, but yields at large distances ($r \gtrsim 1$ fm) to the formation of symmetry-breaking gluon and quark condensates. The approach is applied to the evolution of a fragmenting $q\bar{q}$ pair with its generated gluon distribution, starting from a large hard scale $Q^2$. The modification of the gluon distribution arising from the coupling to the nonperturbative collective field results eventually in a complete condensation of gluons. Color flux tube configurations of the gluons in between the $q\bar{q}$ pair are obtained as solutions of the equations of motion. With a reasonable parameter choice, the associated energy per unit length (string tension) comes out $\simeq 1$ GeV/fm, consistent with common estimates.

I. INTRODUCTION

The physics of QCD exhibits different relevant excitations at different length scales. At space-time short distances (below 1 fm) the relevant degrees of freedom are quarks and gluons whose interactions are well described by perturbative QCD [1, 2]. The long distance physics on the other hand is governed by the hadronic degrees of freedom, and the particles which are observed at large scales are hadrons whose interactions are well described by chiral models [3]. The change of resolution of our microscope with which we probe the physics of QCD is formally described by a renormalization group equation, or evolution equation, that determines the scale dependence of the theory [4-6].

The transition from the short distance (high momentum transfer) regime to the long distance (low energy) domain can be cast in terms of an evolution equation for an effective QCD action that embodies both fundamental partonic degrees and hadronic degrees of freedom. By increasing the distance scale (decreasing the momentum scale), the evolution [7] of the effective field theory must lead from one set to the other set of degrees of freedom. Experiments on high energy QCD processes, such as $e^+e^-$ annihilation, deep inelastic $ep$ scattering, Drell Yan, etc., strongly support the conception that the observed parton fragmentation into hadrons is a universal mechanism. Moreover, the dynamical transformation of color charged quarks and gluons in high energy QCD processes into colorless hadrons is commonly believed to be a local phenomenon [8]. Thus, a consistent description of the local hadronization mechanism must be independent of the details of the partons' prehistory and should in principle apply also to hadron-hadron, hadron-nucleus, or nucleus-nucleus collisions.

To date most of the theoretical tools to study properties of QCD are inadequate to describe the dynamics of the transformation from partonic to hadronic degrees of freedom: Perturbative techniques are limited to the deconfined, short distance regime of high energy partons [9], QCD sum rules [10], and effective low energy models [11] are restricted to the long distance domain of hadrons, and lattice QCD [12] lacks the capability of dynamical calculations concerning the quark-gluon to hadron conversion. On the other hand, phenomenological approaches to parton fragmentation [13] are mostly based on hadronization models with ad hoc prescriptions to simulate hadron formation from parton decays.

In this paper I follow a rather different, universal approach to the dynamic transition between partons and hadrons based on an effective QCD field theory description, as recently proposed in Ref. [14]. In the spirit of the aforementioned evolution of effective field theory from high energy to low energy scales [5, 7], the key element is to project out the relevant degrees of freedom for each kinematic regime and to embody them in an effective QCD Lagrangian which recovers QCD with its scale and chiral symmetry properties at high momentum transfer, but yields at low energies the formation of symmetry-breaking gluon and quark condensates including excitations that represent the physical hadrons. In Sec. II, I will first formulate the general field theoretical framework. On the basis of the dual vacuum picture of coexisting perturbative and nonperturbative domains an effective action is constructed that embodies the correct scale and symmetry properties of QCD. The concept is here more phenomenologically motivated than the re-
lated formal approach of Ref. [7]. However, there appears to be a clear correspondence between these two descriptions. In Sec. III, I shall demonstrate the applicability of this effective QCD field theory to the dynamics of parton-hadron conversion by exemplarily considering the evolution of gluons produced by a fragmenting quark antiquark pair. The change of the gluon distribution in the presence of a confining composite field is studied and flux tube solutions of the gluon field resulting from the equations of motion are analyzed in terms of the string tension that characterizes the effective confinement potential. Various perspectives of the approach are discussed in Sec. IV, in particular the applicability to the QCD phase transition and high density QCD.

II. EFFECTIVE QCD FIELD THEORY WITH SPONTANEOUS SYMMETRY BREAKING

The basic idea is that the vacuum state in QCD can be visualized as a color dielectric medium [19], described by a phenomenological Lorentz scalar and color singlet field $\chi$ whose vacuum expectation value (VEV) is nonvanishing: $\langle 0 | \chi | 0 \rangle \neq 0$. The field $\chi$ plays the role of a collective field in the long wavelength limit; for instance $\chi$ could be composed of $f_{abc}F_{\mu\nu}^a F_{\gamma\delta}^b F_{\lambda}^c$ or $(F_{\mu\nu}^a F_{\mu\nu}^a)^2$, or other combinations [20], where $F_{\mu\nu}^a$ is the usual SU(3) field strength tensor. Now suppose one produces an excitation in this medium (i.e., the vacuum characterized by $\chi_0$) by introducing an external current. To be specific, consider the creation of a $q\bar{q}$ pair by a virtual photon from $e^- e^-$ annihilation. Then the natural consequence of the “antiscreening” nature [19] of QCD as non-Abelian gauge theory, the $q\bar{q}$ pair will repel the medium around it and create a hole of some small volume $\Omega$ in the vacuum, inside which the properties are different from outside: Inside $\Omega$, at small distances $r \ll \Omega^{1/3}$, one has $\langle \chi \rangle \neq \chi_0$ and the relevant degrees of freedom are the microscopic colored quanta (the $q\bar{q}$ plus its emitted bremsstrahlung gluons). Because of asymptotic freedom, they behave approximately as free particles and the usual perturbative description applies. Thus, $\langle \chi \rangle = 0$ as $r \to 0$. Outside $\Omega$, at distances $r \gg \Omega^{1/3}$, i.e., in the long wavelength limit, the physics can be described by the collective, macroscopic field $\chi$ with VEV $\langle \chi \rangle = \chi_0$. Since $\chi_0$ is assumed to characterize the long range order of the infinite volume QCD vacuum, the change from $\langle \chi \rangle = 0$ to $\langle \chi \rangle = \chi_0$ can be interpreted as the restoration of the long range order associated with confinement. In the above example of a fragmenting $q\bar{q}$ pair, the change of the $\chi$ field is generated by the dynamics of the $q\bar{q}$ system itself as it spreads out in space-time. Thus, the interaction between the quanta and the collective field $\chi$ can provide a dynamical interpolation between the short distance and the long range properties of QCD in the process of parton-hadron conversion.

Thus, in order to quantify this picture, the goal is to construct an effective field theory that describes the dynamics of both partonic and hadronic degrees of freedom and their interplay. The approach is based on the concept of the effective action [4, 7], which will be represented here as $(r \equiv r^\mu$ denotes the space-time four-vector)

$$S_{\text{eff}} = \int d^4r \left[ \mathcal{L}[\psi, A] + \mathcal{L}[\chi, U] + \mathcal{L}[\psi, A, \chi] \right].$$

(1)

The three contributions to the action, which will be discussed below, correspond to the QCD Lagrangian with the quark ($\psi_j$) and gluon fields ($A^a_{\mu}$), an effective low energy Lagrangian introducing composite fields $\chi$ and $U$, and a term that couples the “microscopic” fundamental quark and gluon degrees of freedom to the “macroscopic” fields $\chi$ and $U$ which represent the hadronic degrees of freedom.

A. $\mathcal{L}[\psi, A]$

The QCD Lagrangian in (1) contains the gluon fields $A^a_{\mu}$ coupled to massless quark fields $\psi_i$ ($i = 1, \ldots, N_f$),

$$\mathcal{L}[\psi, A] = -\frac{1}{4} F_{\mu\nu}^a F_{\mu\nu}^a + \bar{\psi}_i \left[ i \gamma_\mu \partial^\mu - g_\ast A^a_{\mu} \gamma_a T^a \right] \psi_i + \mathcal{L}_{\text{gauge}} + \mathcal{L}_{\text{ghost}}.$$

(2)

Here $F_{\mu\nu}^a = \partial^\mu A^a_{\nu} - \partial^\nu A^a_{\mu} + g_s f_{abc} A^b_{\mu} A^c_{\nu}$ is the gluon field strength tensor. The subscripts $a, b, c$ label the color components and $g_s$ denotes the color charge related to $\alpha_s = g_s^2/(4\pi)$. The $T_a$ are the generators of the SU(3) color group, satisfying $[T_a, T_b] = i f_{abc} T^c$ with the structure constants $f_{abc}$. The gauge-fixing term $\mathcal{L}_{\text{gauge}} = (1/2a) (\eta_a A^a_{\mu})^2$ with gauge parameters $a$ and $\eta_a$. The contribution of Faddeev-Popov ghost fields $\zeta$, $\mathcal{L}_{\text{ghost}} = (\delta_{\mu\nu} \partial_\mu \eta_a A^a_{\nu})$, will be irrelevant later on, because a physical gauge $\gamma A = 0$ can be fixed, which eliminates the presence of ghosts.

The Lagrangian (2) is well known to be invariant under chiral transformations [3]. At the tree level it is also invariant under scale transformations $r_\mu \to r_\mu = e^{\Delta} r_\mu$ [15], generated by a so-called dilaton charge $D(t) = \int d^3r J^S_0 (r)$, where $J^S_\mu$ is the scale current and $D(t, \phi(r)) = i (r_\mu \partial^\mu + d_\phi) \phi(r)$ for a generic quantum field $\phi$ with scale dimension $d_\phi$. The convention is $d_A = 1$ for gauge boson fields and $d_\phi = 3/2$ for fermion fields. It follows that $\mathcal{L}(\psi, A)$ has scale dimension 4 so that $D_t \mathcal{L}(\psi, A) = 0$ and therefore massless QCD proves to be scale invariant at the tree level.

At high energies and short space-time distances, asymptotic freedom leads to unconfined gluon and quark fields in (2). However, in the physical world these color degrees of freedom are confined, and both chiral and scale symmetry are explicitly broken. To describe the dynamics of the symmetry breakdown of the transition between the perturbative, scale, and chiral-invariant regime and the nonperturbative world with broken symmetries, one needs to supplement (2) (by adding $\Delta \mathcal{L} = \mathcal{L}[\chi, U] + \mathcal{L}[\psi, A, \chi]$) to construct an effective description such that at high energies the fully symmetric QCD phase is recovered, but at low energies massive hadrons emerge.
B. $\mathcal{L}[\chi, U]$

The specific form of $\mathcal{L}[\chi, U]$ in (1) is adopted from Refs. [16, 17], where an effective low energy Lagrangian was constructed, guided by the scale and chiral symmetry properties of the QCD Lagrangian. The construction is based on the observation that even massless QCD is no longer scale invariant when going beyond the tree level, because of the scale anomaly [15]

$$\partial^\mu J^\mu = \beta(g_2)/(2g_a) F_{\mu\nu} F^{\mu\nu},$$

where $J^\mu$ is the scale current. In addition chiral invariance breaks down when finite quark masses are taken into account. As a consequence, the QCD energy momentum tensor $\theta_{\mu\nu}$ exhibits the well-known trace anomaly [18]

$$\mathcal{L}[\chi, U] = \frac{1}{2} (\partial_\mu \chi)(\partial^\mu \chi) - b \left( \frac{1}{4} \chi^4 + \chi^4 \ln \left( \frac{\chi}{\epsilon^{1/4} x_0} \right) \right) + \frac{1}{4} \left( \frac{x}{\chi_0} \right)^2 \text{Tr} \left[ (\partial_\mu U)(\partial^\mu U^\dagger) \right]$$

$$- c \left( \frac{x}{\chi_0} \right)^3 \text{Tr} \left[ m_q(U + U^\dagger) \right] - \frac{1}{2} \left( \frac{x}{\chi_0} \right)^4 m_\phi^2 \phi_0^2.$$

This form introduces a scalar gluon condensate field $\chi$ and a pseudoscalar quark condensate field $U = f_\pi \exp \left( i \sum_{j=0}^8 \lambda_j \phi_j / f_\pi \right)$ for the nonet of the meson fields $\phi_j (f_\pi = 93 \text{ MeV}, \text{Tr} \lambda_j \lambda_j = 2 \delta_{jj}, UU^\dagger = f_\pi^2)$, with nonvanishing vacuum expectation values

$$\chi_0 = \langle 0 | \chi | 0 \rangle \neq 0$$

$$U_0 = c \langle 0 | U + U^\dagger | 0 \rangle \neq 0$$

that explicitly break scale and, respectively, chiral symmetry. In (4), $b$ is related to the conventional bag constant $B$ by $B = b x_0^4 / 4$, $c$ is a constant of mass dimension 3, $m_q = \text{diag}(m_u, m_d, m_s)$ is the light quark mass matrix, and $m_\phi^2$ is an extra U(1)-breaking mass term for the ninth pseudoscalar meson $\phi_0$.

Notice that the anomaly constraint (3) is modeled by the second and fourth terms in (4) with the correspondence

$$\left\langle 0 \left| \frac{\beta(g_2)}{4g_a} F_{\mu\nu} F^{\mu\nu} \right| 0 \right\rangle = -b \chi_0^4$$

and

$$\langle 0 \left| \bar{q} q \right| 0 \rangle = c \left( \frac{x}{\chi_0} \right)^3 \langle 0 \left| U + U^\dagger \right| 0 \rangle.$$
Other forms used in the literature are, e.g., \( \kappa(\chi) = |1 - (\chi/\chi_0)^n|^m \) \[23\] (Friedberg and Lee originally proposed \( n = m = 1 \)).

Similarly, absolute confinement can be ensured also for quarks by coupling the quark fields to the \( \chi \) field through \[24\]
\[
g(\chi) = g_0 \left( \frac{1}{\kappa(\chi)} - 1 \right),
\]
which leads to an effective confinement potential with the masses of the quarks inside approximately equal to the current masses, but at \( \chi = \chi_0 \) it generates an infinite asymptotic quark mass (the value of \( g_0 \) is irrelevant in the present paper).

**D. Equations of motions**

To summarize to this end, the complete effective action (1) is determined by the Lagrangian

\[
\mathcal{L}_{\text{eff}} = \mathcal{L}[\psi, A] + \mathcal{L}[\chi, U] + \mathcal{L}[\psi, A, \chi]
\]
\[
= -\frac{1}{4} \kappa(\chi) F_{\mu \nu} A^\mu A^\nu + \bar{\psi}_i \left( i \gamma_{\mu} \partial^\mu - g_s \gamma_{\mu} A^\mu_a T_a - g(\chi) \right) \psi_i
\]
\[
+ \frac{1}{2} (\partial_{\mu} \chi)(\partial_{\mu} \chi) + \frac{1}{4} \text{Tr} \left[ (\partial_{\mu} U)(\partial_{\mu} U^\dagger) \right] - V(\chi, U),
\]

(13)

plus the terms \( \mathcal{L}_{\text{gauge}} \) and \( \mathcal{L}_{\text{ghost}} \) of (2). The potential \( V \) is given by

\[
V(\chi, U) = b \left[ \frac{1}{4} \chi_0^4 + \chi^4 \ln \left( \frac{\chi}{\chi_0} \right) \right] + \frac{1}{4} \left[ 1 - \left( \frac{\chi}{\chi_0} \right)^2 \right] \text{Tr} \left[ (\partial_{\mu} U)(\partial_{\mu} U^\dagger) \right]
\]
\[
+ c \text{Tr} \left[ \hat{m}_q (U + U^\dagger) \right] \left( \frac{\chi}{\chi_0} \right)^3 + \frac{1}{2} m_s^2 \phi_0^2 \left( \frac{\chi}{\chi_0} \right)^4,
\]

(14)

which has its minimum when \( \chi = \chi_0 = (0)|0(0) \) and equals the vacuum pressure (bag constant) \( B = b \chi_0^4/4 \) at \( \chi = 0 \). Typical forms of \( V(\chi, U) \) for different values of \( B \) and \( m_q \) are depicted in Fig. 1.

The effective field theory defined by (1) and (13) represents a description of the duality of partonic and hadronic degrees of freedom by coupling the high energy QCD phase with unconfined gluon and quark degrees of freedom to a low energy QCD phase with confinement and broken chiral symmetry which contains a gluon condensate (6) and a quark-antiquark condensate (7). Small oscillations about the minimum of the potential \( V(\chi, U) \) are to be interpreted as physical hadronic states that emerge after symmetry breaking. They include \[17\] (i) glueballs and hybrids as quantum fluctuations in the gluon condensate \( \chi_0 \), (ii) pseudoscalar mesons as excitations of the quark condensate \( U_0 \), (iii) the pseudoscalar flavor singlet meson \( \phi_0 \), and (iv) baryons as nontopological solitons \[25\].

The field equations which derive from (1) and (13) are

\[
[\gamma_{\mu} (i \partial_{\mu} - g_s A^\mu_a T_a) - g(\chi)] \psi_i = 0,
\]

(15)

\[
\partial_{\mu} [\kappa(\chi) F^\mu_a] = -g_s \kappa(\chi) f_{abc} A^\mu_a F^\mu_b + g_s \bar{\psi}_i e^\nu T_a \gamma^\nu \psi_i,
\]

(16)

\[
\partial_{\mu} \partial^\mu \chi + \frac{\partial V(\chi, U)}{\partial \chi} + \frac{1}{4} \frac{\partial \kappa(\chi)}{\partial \chi} F^\mu_a F^\mu_a + \frac{\partial g(\chi)}{\partial \chi} \psi_i = 0,
\]

(17)

\[
\partial_{\mu} \partial^\mu U + \frac{\partial V(\chi, U)}{\partial U} + \partial_{\mu} \frac{\partial V(\chi, U)}{\partial (\partial_{\mu} U)} = 0.
\]

(18)
Notice that the $U$ field does not couple directly to the quark and gluon fields. Per construction [17], the dynamics of the quark condensate field $U$ is solely driven by the gluon condensate field $\chi$. It is important to realize that the interplay between the $\chi$ field and the quark and gluon fields $\psi$ and $A$ is the crucial element of this approach.

It is also evident from the equations of motions and the form of the potential (14) that in the short distance regime when $\chi = 0$ as $r \to 0$ and $\kappa(\chi) = 1$, the system of equations decouples and reduces to the usual Yang-Mills equation. Similarly, in the long wavelength limit $r \to \infty$, one has $\chi \to \chi_0$, $U \to U_0$, and $\kappa(\chi) \to 0$, so that the dynamics in this case is completely described by the equations for the effective fields $\chi$ and $U$.

E. Comments

The following remarks concerning the effective Lagrangian (13) are important. (a) At short distances or high momentum transfers the exact QCD Lagrangian (2) is recovered, since $\chi = U = 0$ and $\kappa(\chi) = 1$ [i.e., $\xi(\chi) = 0$] and $g(\chi) = 0$, whereas the long distance QCD properties emerge as $\chi/\chi_0 \to 1$ and $U/U_0 \to 1$ [17] and no colored quanta survive. The transition from one set of degrees of freedom ($\psi,A$) to the other ($\chi,U$) corresponds to consecutively integrating out all colored quantum fluctuations and absorbing them effectively in the collective color singlet fields.

(b) The problem of double counting degrees of freedom has to be carefully inspected. Although it does not arise in one-loop calculations (to which I will restrict here), processes with, e.g., two-gluon exchange could also be contained in the exchange of a color singlet $\chi$ quantum. A minimal possibility to avoid this problem is a rigid separation of high and low momentum modes, by introducing a characteristic scale $Q_0$. Above $Q_0$ the physics is described in terms of quark gluon degrees and below $Q_0$ the dynamics is governed by the collective degrees of freedom [7].

(c) $L[\chi,U]$ for the composite fields embodies the correct QCD scaling and chiral properties and accounts for the important anomaly (3) of the physical energy-momentum tensor of QCD. The coupling between quarks and gluons to the composite field $\chi$ in $L[\psi,A,\chi]$ can be interpreted in analogy to a thermodynamic system in equilibrium with a heat bath, with a net flow of energy between the system and the heat bath environment such that the bare energy of the system is not conserved. However, the free energy of the system, here high momentum quarks and gluons, is constant [26]. It corresponds to the conserved energy-momentum tensor $\theta_{\mu\nu}$ with its nonzero trace (3).

(d) There is no need for explicit renormalization of $\Delta L = L[\chi,U] + L[\psi,A,\chi]$. The composite fields $\chi$ and $U$ are already interpreted as effective degrees of freedom with loop corrections implicitly included in $\Delta L$ and it would be double counting to add them again. Moreover, in the present approach the low energy domain of $L[\chi,U]$ is per construction bounded from above by the onset of the high energy regime described by $L[\psi,A]$.

In correspondence to item (b) the scale $Q_0$ that separates the two domains, provides an “ultra-violet” cutoff for $L[\chi,U]$, and at the same time an infrared cutoff for $L[\psi,A]$.

This effective field theory approach offers a wide range of physical applications and can be extended and refined in various directions, as discussed in Sec. IV. The scope of the remainder of this paper is, however, conceived as an exemplary demonstration of how the dynamics of parton-hadron conversion emerges within this framework.

III. CONFINEMENT OF GLUONS IN A FRAGMENTING $Q\bar{Q}$ SYSTEM

The effective QCD field theory defined by (13) is readily applicable to describe the dynamic evolution from perturbative to nonperturbative vacuum in high energy processes. In accord with the symmetry-breaking formalism of Sec. II, the parton-hadron transition can be visualized as the conversion of high momentum colored quanta of the fundamental quark and gluon fields into color neutral composite states that are described by the condensate fields $\chi$ and $U$ and their excitations.

In the following I shall consider as an example the fragmentation of a $q\bar{q}$ jet system with its emitted bremsstrahlung gluons and describe the evolution of the system as it converts from the parton phase to the hadronic phase. The process is illustrated in Fig. 2: A timelike virtual photon in an $e^+e^-$ annihilation event

![FIG. 2. Schematics of the parton shower evolution of a fragmenting $q\bar{q}$ pair with its gluon configuration as the virtualities of the partons gradually degrade, starting from the hard scale $Q^2$. At large gluon virtualities $k^2$ the shower develops by perturbative branching processes, but at $k^2 \simeq Q_0^2$ nonperturbative fusion and friction processes set in, such that at $k^2 = \Lambda^2$ no colored fluctuations remain.](image-url)
with large invariant mass \( Q^2 \gg \Lambda^2 \) is assumed to produce a \( q \bar{q} \) pair which initiates a cascade of sequential gluon emissions. (Here and in the following \( \Lambda \) denotes the fundamental QCD scale.) The early stage is characterized by emission of “hot” gluons far off the mass shell in the perturbative vacuum. Subsequent gluon branchings yield “cooler” gluons with successively smaller virtualities, until they are within \( Q_0^2 \), where \( Q_0 \) is of the order of \( m_\chi \equiv 4bX_0^2 \sim 1 \text{ GeV} \). At this point condensation sets in, or loosely speaking, the “cool” gluons are absorbed by the color neutral gluon condensate field \( \chi \), the particle excitations of which must then decay into physical hadrons by means of some local interaction in the nonperturbative vacuum. A similar picture holds for the \( U \) field.

It is well known that the bulk of produced particles stems from rather soft gluon emissions that are characterized by small values \( x \) of the fraction of the initial energy. Secondary production of \( q \bar{q} \) pairs is comparably rare on the perturbative level. It is therefore reasonable to neglect the quark degrees of freedom and study the purely gluonic sector. Furthermore, it is convenient to work in a physical (axial) gauge for the gluon fields, \( \eta \cdot A = 0 \), by choosing the gauge vector in (2) as \( \eta_\mu = n_\mu \) with \( n \) being spacelike and constant, in which case the ghost contribution vanishes. Consequently, the equations of motion (15)–(18) reduce to

\[
\begin{align*}
\partial_\mu [\kappa(\chi) F^{\mu\nu}] &= -g_\mu \kappa(\chi) F_{\nu a} A_{\mu a} F^{\mu\nu}, \\
\partial_\mu \partial^\nu \chi &= -\frac{\partial V(\chi)}{\partial \chi} - \frac{\partial \kappa(\chi)}{\partial \chi} F_{\mu\nu a} F^{\mu\nu a}, \\
\partial_\mu \partial^\nu U &= -4 c \left( \frac{\chi}{\chi_0} \right)^3 \text{Tr}[m_q] .
\end{align*}
\]

The solution of these equations is a still formidable task, because not only the gluon fields but also \( \chi \) and \( U \) are quantum operators. To make progress, I will now proceed by (i) treating the quantum gluon fields perturbatively, and (ii) employing the mean field approximation for the composite fields \( \chi \) and \( U \). Representing

\[
\chi(r) = \hat{\chi}(r) + \tilde{\chi}(r) ,
\]

where \( \hat{\chi} \) is a c number and \( \tilde{\chi} \) a quantum operator (similarly for \( U \)), the mean field approximation is obtained by neglecting the quantum fluctuations \( \tilde{\chi} \) and keeping only \( \hat{\chi} \). Thus, the approximations (i) and (ii) correspond to the semiclassical limit in which gluonic quantum fluctuations interact with a classical mean field. To a good approximation this should provide a reasonable description: first, because renormalization-group-improved QCD perturbation theory allows for an accurate description of the evolution of the gluon field [27] at short distances where \( \chi = 0 \), and second, because the dynamics of the system around \( \chi = \hat{\chi} \) is governed by a large number of virtual excitations, corresponding to coherent modes of field quanta, so that a quasiclassical mean field description should be applicable in the low energy regime [20].

A. Evolution of the gluon distribution in the presence of the collective field \( \chi \)

As I will show now, the equations of motion (19)–(21) simplify to a perturbative evolution equation for the gluon distribution which is coupled to the equation for the mean field \( \hat{\chi} \). The key problem is the first equation, since the gluon fields \( A^{\mu} \), or equivalently \( F^{\mu\nu} \), drive the dynamics of the \( \chi \) field which in turn feeds back via \( \kappa(\chi) \). As mentioned before, the \( U \) field does not couple directly to the gluon field. The procedure in the following is therefore to “solve” Eq. (19) as a function of \( \kappa \) and then to insert the solution into (20), so that one is left (aside from the simple third equation) with a single equation for \( \chi \), which, however, is nonlinear.

Solving the equation of motion (19) for the gluon field is equivalent to the calculation of the complete Greens function with an arbitrary number of gluons. Instead, I will restrict to evaluate the two-point Greens function only (Fig. 3), i.e., the full gluon propagator which includes both the one-loop order gluon self-interaction through real and virtual emission and absorption, and the effective interaction with the confining background field \( \chi \). In the framework of “jet calculus” [28], this gluon propagator, denoted as \( D_\mu(x, k^2; x_0, Q^2) \), describes how

![Diagram](image-url)

FIG. 3. Diagrammatic representation of the two-point Greens function of gluons, including both the gluon (self-)interactions and the effective interaction with the confining background field \( \chi \) (indicated by the dashed lines). This gluon propagator describes the evolution of a gluon from a chosen cascade branch in \( x \) and \( k^2 \), starting from \( x_0 \) and \( Q^2 \).
a gluon, produced with an invariant mass $Q^2$, evolves in the variable $x$ (momentum or energy fraction) and the virtuality $k^2$ (or transverse momentum $k_T^2$) through these interactions. To one-loop order, it is obtained by calculating the corresponding cut diagrams. In the present case, one has, in addition to the usual gluon branching and fusion processes, $g \to gg$ and $gg \to g$, contributions from energy transfer and two gluon annihilation processes $g \to g\chi$ and $gg \to \chi$, respectively. This is illustrated in Fig. 3.

To write down the determining equation for the gluon propagator $D_g$, it is convenient to employ light cone variables, defined by the identification of components of four-vectors as

\[ k^\mu = (k^+, k^-, k_\perp), \quad k^\pm = \frac{1}{\sqrt{2}} (k^0 \pm k^3), \]

\[ k_\perp = (k^1, k^2). \]  \hspace{1cm} (23)

The $k^+$ component of a particle’s momentum, the light cone momentum, is always positive definite, $k^+ > 0$, and the light cone energy $k^- = (k_\perp^2 + m^2)/(2k^+)$ is also positive. Furthermore, the light-cone-time $\tau^+ = (t+z)/\sqrt{2}$ is conjugate to $k^-$ and the light cone coordinate $\tau^-$ is conjugate to $k^+$. The invariant momentum space element is

\[ \frac{d^3k}{(2\pi)^2E} = \frac{d^4k}{(2\pi)^4} \delta^+(k^2 - m^2) \frac{dk^+ dk_\perp}{16\pi^3 k^+}. \]  \hspace{1cm} (24)

Choosing the light cone gauge for the gluon fields, $\eta \cdot A = A^+ = -A^- = 0$, results in well-known simplifications in the perturbative analysis of light-cone-dominated processes and has the advantage that there are neither negative norm gluon states nor ghost states present [30]. As a consequence only the transverse components $A_\perp^i$ ($i = 1,2$) are dynamical field variables, since $A^\perp$ is identically zero and $A^- = 0$ is determined at any “time” $\tau^+$ by $A_\perp^1$ and $A_\perp^2$. The particular choice $\eta = (p_q + p_{\bar{q}})/2$ has the advantage that interference terms do not contribute [2] to leading logarithmic accuracy (they are suppressed $\sim 1/k^2$).

Therefore, in the leading logarithmic approximation (LLA) [31, 9, 27, 32], it is enough to realize that for every choice of $b$ (Fig. 3, top), one can group the other gluons in a unique way to groups forming dressed rungs of a ladder (Fig. 3, middle) whose discontinuity is taken (Fig. 3, bottom).

Introducing the variable $x = k^+ / P^+$ (the light cone fraction), and parametrizing the momenta of initial quark and antiquark as $P \equiv p_q + p_{\bar{q}}$ with

\[ P^+ = Q, \quad P^- = \frac{4m_q^2}{2P^+}, \quad P_\perp = 0, \]  \hspace{1cm} (25)

i.e., $P^2 = Q^2$, where as before $Q$ denotes the invariant mass of the timelike photon that creates the pair, the determining equation for the gluon propagator $D_g(x, x_0; k^2, Q^2)$ can now be represented in the form (cf. Appendix A)

\[ D_g(x, x_0; Q^2) = x_0 \delta(x - x_0) \delta(k^2 - Q^2) \frac{1}{k^2} \int d^4k' \int_{Q_0^2}^{k_1^2} \frac{d^4k'}{k'^2} \int_0^1 \frac{dx'}{x'} w(x', x, k), \]

\[ + \frac{1}{k^2} \int_{Q_0^2}^{k^2} \frac{d^4k'}{k'^2} \int_0^1 \frac{dx'}{x'} w(x', x, k^2) D_g(x', x_0; Q^2) F_g(k^2, Q_0^2). \]  \hspace{1cm} (26)

This equation has a simple physical significance: The first term is the inclusive sum of virtual emissions and reabsorptions, and therefore does not change the number of gluons in the gluonic wave function of the fragmenting $Q\bar{Q}$ pair, whereas the second term describes the change of the gluon distribution as a result of real decay or fusion processes. The Sudakov form factor

\[ F_g(Q^2, k^2) = \exp \left[ -\int_{k^2}^{Q^2} \frac{dk'}{k'^2} w_g(k'^2) \right] \]  \hspace{1cm} (27)

is the probability a gluon propagates like a bare, noninteracting particle while degrading its virtuality from $Q^2$ to $k^2$. As the gap between $Q^2$ and $k^2$ grows, such a fluctuation becomes increasingly unlikely. The total interaction probability

\[ w_g(k^2) = \int_0^1 \frac{dx}{x} \int_0^k \frac{dx'}{x'} w(x', x, k^2) \]  \hspace{1cm} (28)

is the integral over the inclusive probability for all possible gluon interaction processes $i$:

\[ w(x', x, k^2) = \sum_{\text{processes } i} w_{(i)}(x', x, k^2). \]  \hspace{1cm} (29)

The normalization is such that

\[ 1 = F_g(Q^2, Q_0^2) + F_g(Q^2, k^2) \int_{Q_0^2}^{Q^2} \frac{dk'}{k'^2} \] \[ \times \frac{w_g(k'^2)}{k'^2} = \frac{1}{x} \int_{Q_0^2}^{Q^2} \frac{dk'}{k'^2} \frac{w_g(k'^2)}{k'^2}, \]  \hspace{1cm} (30)

in accordance with unitarity (probability) conservation. Multiplying (26) by $F_g^{-1}$, differentiating, and accounting for (30) yields

---

1 In the present case of $q\bar{q}$ jet evolution, the contribution of perturbative two-gluon fusion processes $gg \to g$ for $k^2 > \Lambda^2$ is very small [29], but the nonperturbative gluon recombination $gg \to \chi$ in the range $Q_0^2 \sim k^2 > \Lambda^2$ is of essential importance in order to achieve complete confinement.
\[ k^2 \frac{\partial}{\partial k^2} D_g(x, k^2; x_0, Q^2) = \int_0^1 dx' x' w(x', x, k^2) D_g(x', k^2; x_0, Q^2) - w_g(k^2) D_g(x, k^2; x_0, Q^2). \] (31)

As summarized in the Appendixes, one obtains, for the individual interaction probabilities \( w_{ij} \) to one-loop order [with the assignment \( x_1 \to x_2, (x_2 - x_1) \to x_2 \) for branchings and \( x_1, (x_2 - x_1) \to x_2 \) for fusions],

\[
\begin{align*}
w_{g\to gg}(x_1, x_2, k^2) &= \frac{\alpha_s(k^2)}{2\pi} \gamma_{g\to gg} \frac{x_2}{x_1}, \\
w_{g\to gg}(x_1, x_2, k^2) &= \frac{\alpha_s(k^2)}{2\pi} \left[ \frac{8\pi^2}{k^2 \Lambda^2} \frac{c_{gg\to g}}{x_2} \right] \gamma_{g\to gg} \frac{x_1}{x_2}, \\
w_{g\to g\chi}(x_1, x_2, k^2) &= \frac{\lambda_\chi(k^2)}{2\pi} \gamma_{g\to g\chi} \frac{x_2}{x_1}, \\
w_{g\to g\chi}(x_1, x_2, k^2) &= \frac{\lambda_\chi(k^2)}{2\pi} \left[ \frac{8\pi^2}{k^2 \Lambda^2} \frac{c_{g\chi\to g}}{x_2} \right] \gamma_{g\to g\chi} \frac{x_1}{x_2},
\end{align*}
\] (32)

where \( c_{gg\to g} = c_{g\chi\to g} = 1/8 \) and

\[
\begin{align*}
\gamma_{g\to gg}(z) &= 2 C_A \left( z(1-z) + \frac{z}{1-z} + \frac{1-z}{z} \right), \\
\gamma_{g\to g\chi}(z) &= \frac{1}{4} \left( \frac{1 + z^2}{1 - z} \right), \\
\gamma_{g\to g\chi}(z) &= 8 \left( z^2 - z + \frac{1}{2} \right).
\end{align*}
\] (33)

Here \( C_A = N_c = 3 \), and \( z \) is the fraction of \( x \) values of daughter to mother gluons. In (32),

\[
\alpha_s(k^2) = \left[ b \ln \left( \frac{k^2}{\Lambda^2} \right) \right]^{-1}, \quad b = \frac{11N_c - 2N_f}{12\pi}
\] (34)

is the one-loop-order QCD running coupling (in the present case \( N_f = 0 \)), and

\[
\lambda_\chi(k^2) = \frac{\xi_\chi(k^2)}{4\pi}
\] (35)

denotes the coupling to the \( \chi \) field in momentum space, with \( \xi_\chi \) denoting the Fourier transform of \( \xi(\chi) \) in (8).

Equation (26) for the propagator \( D_g(x, k^2; x_0, Q^2) \) corresponds the evolution equation for the gluon distribution \( g(x, k^2_\perp) \), which is defined [33] as average number of gluons at "light cone time" \( r_+ = 0 \) in the multigluon state \( |P\rangle \) with light cone fractions \( x \equiv k^+/P^+ \) in a range \( dx \) and transverse momenta in a range \( d^2k_\perp \):

\[
x g(x, k^2_\perp) = \frac{1}{P^+} \int \frac{dr^-dr_{\perp}}{(2\pi)^3} e^{-i(k^r - k_{\perp} \cdot r_{\perp})} \langle P | F_{a\mu}(0, r^-, r_{\perp}) F_{a\mu}(0, 0, 0, 0_{\perp}) |P \rangle.
\] (36)

Thus, as is evident from Fig. 3, the probability for finding a gluon with \( x \) and \( k^2_\perp \) is given by the identification

\[
g(x, k^2_\perp) = \left. D_g(x, k^2; 1, Q^2) \right|_{k^2 = k^2_\perp}.
\] (37)

On account of the explicit expressions (32)–(35), and taking as evolution variable the gluon transverse momentum \( k^2_\perp \) rather than the invariant mass \( k^2 \) [34], one finally arrives at the master equation for the evolution of the gluon distribution:

---

\[ \text{It is convenient to visualize the initial } q\bar{q} \text{ pair (25) as a single incoming "gluon" with momentum } P, \ i.e., \text{, with } x_0 = 1 \text{ and invariant mass } Q \ (\text{cf. Fig. 3}). \]
\[
\left( k_\perp^2 \frac{\partial}{\partial k_\perp^2} \right) g(x, k_\perp^2) = + \frac{\alpha_s(k_\perp^2)}{2\pi} \int_0^1 dz \left[ \frac{1}{z} g \left( \frac{x}{z}, k_\perp^2 \right) - \frac{1}{2} g(x, k_\perp^2) \right] \gamma_{g\rightarrow gg} (z) \theta (k_\perp^2 - Q_0^2) \\
- \frac{\alpha_s(k_\perp^2)}{2\pi} \left( \frac{\Lambda^2}{k_\perp^2} \right) 8\pi^2 c_{gg\rightarrow g} \int_0^1 dz \left[ g^{(2)} \left( x, \frac{1-z}{z}, k_\perp^2 \right) \right] \\
- \frac{1}{2} g^{(2)} \left[ x, (1-z) x, k_\perp^2 \right] \gamma_{g\rightarrow g} (z) \theta (k_\perp^2 - Q_0^2) \\
+ \frac{\lambda_x(k_\perp^2)}{2\pi} \int_0^1 dz \left[ \frac{1}{z} g \left( \frac{x}{z}, k_\perp^2 \right) - g(x, k_\perp^2) \right] \gamma_{g\rightarrow gx} (z) \\
- \frac{\lambda_x(k_\perp^2)}{2\pi} \left( \frac{\Lambda^2}{k_\perp^2} \right) 8\pi^2 c_{gg\rightarrow x} \int_0^1 dz g^{(2)} \left( x, \frac{1-z}{z}, k_\perp^2 \right) \gamma_{x\rightarrow gg} (z). \tag{38}
\]

This equation reflects the probabilistic parton cascade interpretation of the LLA [35–37], in which the change of the gluon distribution on the left-hand side is governed by the balance of gain (+) and loss (−) terms on the right-hand side. Notice that (38) is free of infrared divergences, because the singularities in (33) at \( z = 0 \) and \( z = 1 \) cancel between gain and loss terms. A diagrammatic illustration of these gain and loss terms is shown in Fig. 4. Also notice that the gluon fusion terms (second and fourth terms) involve the two-gluon distribution \( g^{(2)}(x_1, x_2, k_\perp^2) \), the presence of which causes the evolution equation to be nonlinear.

By means of a Mellin transformation the multiple convolutions of \( z \) integrals inherent in the iteration of Eq. (38) can be converted into products of independent successive interaction probabilities. Let me define the gluon distribution in the moment representation as

\[
g(\omega, k_\perp^2) := \int_0^1 dx \, x^\omega \, g(x, k_\perp^2) = \int_0^\infty dy \, e^{-y \omega} \left[ x g(x, k_\perp^2) \right], \tag{39}
\]

where \( y = \ln(1/x) \), in which the variable \( \omega \) is conjugate to \( \ln(1/x) \), implying that the low \( x \) behavior is determined by small values of \( \omega \). Analogously, the two-gluon distribution is represented as

\[
g^{(2)}(\omega, z, k_\perp^2) := \int_0^1 dx \, x^\omega \, g^{(2)} \left( x, \frac{1-z}{z}, k_\perp^2 \right), \tag{40}
\]

which carries an additional \( z \) dependence. In general \( g^{(2)} \) is a complicated correlation function not available in analytical form, except for certain special cases [28, 38]. It is therefore inevitable on an analytical level to assume a phenomenological form of \( g^{(2)} \) that allows to convert Eq. (38) into a tractable linear form. This can be achieved with the following ansatz of product form [29, 39]:

\[
g^{(2)} \left( x, \frac{1-z}{z}, x, k_\perp^2 \right) = \rho(k_\perp^2) \, g(x, k_\perp^2) \, g \left( \frac{1-z}{z}, x, k_\perp^2 \right), \tag{41}
\]

where \( \rho(k_\perp^2) \) is a parameter that characterizes the magnitude of the probability for finding two gluons at the same point in phase space, depending on their typical transverse size \( r_\perp \sim 1/k_\perp \). Since the two-gluon correlation must become substantial when the number of gluons per unit area \( n_g/(\pi R^2) \) becomes so large that the gluons overlap spatially \( (R_\perp \approx 0.5–1 \text{ fm}) \), one expects that \( \rho \sim 1 \) when \( k_\perp^2 \approx Q_0^2 \) \( (Q_0 = 1 \text{ GeV}) \), and monotonically increasing as \( k_\perp^2 \rightarrow \Lambda^2 \). Using (41) in (40), the two-gluon distribution in the moment representation can be approximated in the soft limit (\( z \ll 1 \)) as

\[
g^{(2)}(\omega, z, k_\perp^2) \approx \rho(k_\perp^2) \frac{x^\omega}{\omega} \, g(\omega, k_\perp^2). \tag{42}
\]

In the moment representation the evolution equation (38) now becomes a linear algebraic equation for the Mellin transformed gluon distribution:

\[
k_\perp^2 \frac{\partial}{\partial k_\perp^2} \, g(\omega, k_\perp^2) = \gamma(\omega, k_\perp^2) \, g(\omega, k_\perp^2), \tag{43}
\]

where \( \gamma(\omega, k_\perp^2) \) plays the role of a generalized anomalous dimension.
\[
\gamma(\omega, k_\perp^2) = \frac{\alpha_s(k_\perp^2)}{2\pi} \theta(k_\perp^2 - Q_0^2) \left[ A_{g \to gg}(\omega) - \left(\frac{\Lambda^2}{k_\perp^2}\right) A_{gg \to g}(\omega) \right] + \frac{\lambda_\chi(k_\perp^2)}{2\pi} \left[ A_{g \to g\chi}(\omega) - \left(\frac{\Lambda^2}{k_\perp^2}\right) A_{gg \to \chi}(\omega) \right]
\]
\equiv \gamma_{\text{QCD}}(\omega, k_\perp^2) + \gamma_\chi(\omega, k_\perp^2).
\]

The functions \(A(\omega)\) are given by
\[
A_{g \to gg}(\omega) = 2C_A \left[ \frac{11}{12} + \frac{1}{\omega - 1} + \frac{1}{\omega + 1} + \frac{1}{\omega + 2} - \frac{1}{\omega + 3} - S(\omega) \right],
\]
\[
A_{g \to g}(\omega) = \frac{\pi^2 \rho}{\omega} A_{g \to gg}(\omega),
\]
\[
A_{g \to g\chi}(\omega) = \frac{1}{4} \left[ \frac{3}{2} - \frac{1}{\omega + 1} - \frac{1}{\omega + 2} - 2S(\omega) \right],
\]
\[
A_{gg \to \chi}(\omega) = \frac{\pi^2 \rho}{2\omega} \left[ \frac{1}{\omega + 1} - \frac{2}{\omega + 2} - \frac{2}{\omega + 3} \right].
\]

where \(S(\omega) = \psi(\omega + 1) - \psi(1)\) with the digamma function \(\psi(z) = d[\ln \Gamma(z)]/dz\) and \(-\psi(1) = \gamma_E = 0.5772\) the Euler constant.

The anomalous dimension \(\gamma(\omega, k_\perp^2)\), Eq. (44), reduces at \(k_\perp^2 \gg \Lambda^2\) to the \(Q_0\) QCD anomalous dimension in the LLA [34], since in this kinematic region \(\kappa(\chi) = 1\) and therefore \(\lambda_\chi = 0\). However, at \(k_\perp^2 \approx Q_0^2, \lambda_\chi(k_\perp^2)\) becomes nonzero, so that the evolution of the gluon distribution receives modifications due to the coupling of gluons to the \(\chi\) field. In the region \(Q_0^2 > k_\perp^2 \geq \Lambda^2\), the perturbative QCD contributions \(\propto \alpha_s\) vanish per construction, so that the gluons solely interact with the \(\chi\) field, the coupling to which increases, because \(\kappa \to 0\), i.e., \(\lambda_\chi \to 1\). This behavior is evident in Fig. 5, which shows \(\gamma(\omega, k_\perp^2)\) versus \(\omega\) for different values of \(k_\perp^2\).

The formal solution of Eq. (43) is
\[
g(\omega, k_\perp^2) = \exp \left\{ \int_{k_\perp^2}^{k_\perp^2} \frac{dk'}{k'} \gamma(\omega, k') \right\},
\]
from which the \(x\) distribution can be reconstructed by considering the inverse Mellin transform
\[
xg(x, k_\perp^2) = \frac{1}{2\pi i} \int_C dw x^{-w}g(\omega, k_\perp^2),
\]
where \(w\) is now a complex variable and the contour of the integration \(C\) runs paralled to the imaginary axis. For the full anomalous dimension (44) this inversion must be done numerically [40].

B. Analytical estimates for \(x\) spectra and gluon multiplicity

To exhibit the main features of the evolution of the gluon distribution in the presence of the \(\chi\) field, it is instructive to make some analytic estimates. Of particular interest is the low \(x\) region, because the soft, small \(x\) gluons are most preferably radiated, but at the same time take away only a very small portion of the total energy. For simplicity I will divide the kinematic range of the \(k_\perp^2\) evolution into two distinct domains as indicated in Fig. 2.

(i) \(Q_0^2 \geq k_\perp^2 \geq \Lambda^2\) and \(k_\perp^2/\Lambda^2 \gg 1\): In this region \(\lambda_\chi \approx 0\) and \(\partial \lambda_\chi/\partial \ln k_\perp^2 \approx 0\), so that (44) reduces to
\[
\gamma(\omega, k_\perp^2) = \frac{\alpha_s(k_\perp^2)}{2\pi} A_{g \to gg}(\omega).
\]

(ii) \(Q_0^2 \geq k_\perp^2 \geq \Lambda^2\) and \(k_\perp^2/\Lambda^2 \to 1\): Here \(\lambda_\chi \to (4\pi)^{-1}\) and \(\partial \lambda_\chi/\partial \ln k_\perp^2 \to 0\), in which case (44) becomes
\[
\gamma(\omega, k_\perp^2) = \frac{\lambda_\chi(k_\perp^2)}{2\pi} A_{g \to g\chi}(\omega) - \left(\frac{\Lambda^2}{k_\perp^2}\right) A_{gg \to \chi}(\omega).
\]

As stated before, the low \(x\) region corresponds to the limit \(\omega \to 0\), so that an expansion of \(\gamma(\omega, k_\perp^2)\) around \(\omega = 0\) gives the dominant contributions at small \(x\). Up to \(O(\omega)\) has in, region (i),
\[
k_\perp^2 \frac{\partial}{\partial k_\perp^2} \ln g(\omega, k_\perp^2) = \frac{\alpha_s(k_\perp^2)}{2\pi} \left[ 2C_A \left( \frac{1}{\omega} - \frac{11}{12} \right) \right]
\]\n\[
\equiv \gamma^{(i)}(\omega, k_\perp^2),
\]

whereas in region (ii) one gets, in the same order of approximation

\[
\gamma^{(ii)}(\omega, k_\perp^2) \text{ of Eq. (44) versus } \omega \text{ for different values of } k_\perp^2.
\]
\[ \kappa_1^2 \frac{\partial}{\partial \kappa_1^2} \ln g(\omega, \kappa_1^2) = -\frac{\lambda_\chi(\kappa_1^2)}{2\pi} \frac{\Lambda^2}{\kappa_1^2} \left[ \frac{8\pi^2}{3\omega} \right] \equiv \gamma^{(ii)}(\omega, \kappa_1^2). \]  

(51)

The accuracy of the expressions \( \gamma^{(i)} \) and \( \gamma^{(ii)} \) in the relevant range of \( \omega \) is exhibited in Fig. 6, where the exact expression \( \gamma(\omega, \kappa_1^2) \) is compared to the small \( \omega \) expansions (50) and (51) at large and small \( \kappa_1^2 \). Evidently the approximation is rather good for \( \omega < 2 \).

Equations (46) and (47) can now be solved analytically with the saddle point method. The \( k_1^2 \) dependence of \( \alpha_s \) is given in (34) and for \( \lambda_\chi = \frac{\bar{\xi}_\chi^2}{4\pi} \), Eq. (35), I will use here the form

\[ \lambda_\chi(\kappa_1^2) = \frac{\theta(Q_0^2 - \kappa_1^2)}{4\pi} \frac{\ln(Q_0^2/k_1^2)}{\ln(Q_0^2/\Lambda^2)}, \]

(52)

which has the required properties that \( \lambda_\chi = 0 \) \((\bar{\xi}_\chi = 0)\) for \( \kappa_1^2 \geq Q_0^2 \) and \( \lambda_\chi \to (4\pi)^{-1} \) \((\bar{\xi}_\chi \to 1)\) for \( \kappa_1^2 \to \Lambda^2 \) as before \( \bar{\xi}_\chi \) denotes the Fourier transform of \( \xi(\chi) \) in Eq. (8). Introducing the variables \( \tilde{f} \) for the region (i) and \( \tilde{u} \) for the region (ii),

\[ \tilde{f}(\kappa_1^2) = \int_{k_1^2}^{Q_0^2} \frac{dk_1'^2}{k_1'^2 \alpha_s(k_1'^2)} = \frac{1}{2\pi b} \ln \left[ \frac{\ln(Q^2/\Lambda^2)}{\ln(k_1^2/\Lambda^2)} \right], \]

\[ \tilde{u}(\kappa_1^2) = \int_{k_1^2}^{Q_0^2} \frac{dk_1'^2}{k_1'^2} \left( \frac{\lambda_\chi(k_1'^2)}{2\pi} \frac{\Lambda^2}{\kappa_1^2} \right) = \frac{\rho}{8\pi^2} \frac{1 - (Q_0^2/k_1^2)}{(Q_0^2/\Lambda^2)(\ln(Q_0^2/\Lambda^2))}, \]

(53)

the combination of (46) and (47) yields, for the kinematic domains (i) \[(\bar{\xi}_\chi = 0),\]

\[ xg(x, \tilde{f}) = \frac{1}{2\pi i} \int_C dw \exp \left[ \omega y + \nu^{(i)}(\omega) \tilde{f} \right] g(\omega, 0), \quad \nu^{(i)}(\omega) = 2C_A \left( \frac{1}{\omega} - \frac{11}{12} \right), \]

\[ xg(x, \tilde{u}) = \frac{1}{2\pi i} \int_C dw \exp \left[ \omega y + \nu^{(ii)}(\omega) \tilde{u} \right] g(\omega, 0), \quad \nu^{(ii)}(\omega) = \frac{8\pi^2}{3\omega}, \]

(54)

where \( y = \ln(1/x) \). The saddle point \( \omega^{(i)}_S \) of the integrand in (54) is determined by the condition

\[ \frac{d}{d\omega} \left\{ \omega y + \nu^{(i)} \tilde{f} \right\} \bigg|_{\omega = \omega^{(i)}_S} = 0 \]

(55)

and similarly \( \omega^{(ii)}_S \). Using the method of steepest descent then gives the following results.

(i) In the region \( Q^2 \geq \kappa_1^2 \geq Q_0^2 \),

\[ xg(x, \kappa_1^2) \mid_{Q^2 \geq \kappa_1^2 \geq Q_0^2} = N_1(x) + G_1(x, \kappa_1^2) \exp \left[ \frac{11CA}{12\pi b} H_1(\kappa_1^2) \right] \exp \left[ \frac{4CA}{\pi b} H_1(\kappa_1^2) \ln \left( \frac{1}{x} \right) \right], \]

\[ N_1(x) = xg(x, \kappa_1^2 = Q^2) = \delta(1 - x)\delta(k_1^2 - Q^2), \]

\[ G_1(x, \kappa_1^2) = \frac{1}{\sqrt{4\pi}} \left[ \frac{CA}{\pi b} H_1(\kappa_1^2) \right]^{1/4} \left[ \ln \left( \frac{1}{x} \right) \right]^{-3/4}, \]

\[ H_1(\kappa_1^2) = \ln \left[ \frac{\ln(Q^2/\Lambda^2)}{\ln(k_1^2/\Lambda^2)} \right]. \]

(56)

(ii) In the region \( Q_0^2 \geq \kappa_1^2 \geq Q_0^2 \),

...
\[ x g(x, k_T^2)\big|_{Q_0^2 \geq k_T^2 \geq \Lambda^2} = N_2(x) - G_2(x, k_T^2) \exp \left[ \frac{4\rho}{3} H_2(k_T^2) \ln \left( \frac{1}{x} \right) \right], \]

\begin{align*}
N_2(x) &= x g(x, k_T^2 = Q_0^2), \\
G_2(x, k_T^2) &= \frac{1}{\sqrt{4\pi}} \left( \frac{\rho}{3} H_2(k_T^2) \right)^{1/4} \left[ \ln \left( \frac{1}{x} \right) \right]^{-3/4}, \\
H_2(k_T^2) &= \frac{1 - (Q_0^2/k_T^2)}{(Q_0^2/L^2)} \ln(Q_0^2/L^2).
\end{align*} \tag{57}

In Fig. 7 the \( x \) spectra of (56) and (57) are shown for different values of \( k_T^2 \) with fixed \( Q_0 = 1 \) GeV. Two different initial distributions were chosen to start the evolution from \( k_T^2 = (3.5 \text{ GeV})^2 \), one flat in rapidity and the other one a Gaussian form. The parameter \( \rho \) introduced in (41) was set equal to 1. For \( k_T^2 \geq Q_0^2 \) the gluon distribution \( x g(x, k_T^2) \) is just the well-known LLA solution with its strong increase at small \( x \) as \( k_T^2 \) decreases. For \( k_T^2 < Q_0^2 \), however, the effect is reversed such that \( g(x, k_T^2) \) decreases as \( k_T^2 \) falls below \( Q_0^2 \). This suppression, which is particularly substantial at small \( x \), reflects the “condensation” of gluons in the collective background field \( \chi \).

The \( k_T^2 \) dependence of the total gluon multiplicity can also be estimated in the above approximation. The gluon multiplicity is given by the \( \omega = 0 \) moment:

\[ N_g(k_T^2) = g(\omega = 0, k_T^2) = \int_0^1 dx g(x, k_T^2). \tag{58} \]

Using Eqs. (43)–(45), one arrives in the soft limit \( z \ll 1 \) [41, 38] at the following integral equations that govern the approximate behavior of the gluon multiplicity for the two cases (i) and (ii):

\begin{align*}
&\text{(i)} \quad k_T^2 \frac{\partial}{\partial k_T^2} N_g(k_T^2) = \frac{\alpha_s(k_T^2)}{2\pi} \left\{ 2C_A \int_{k_T^2}^{Q^2} \frac{dk'}{k'} N_g(k'^2) - \frac{1}{2} N_g(k_T^2) \right\}, \\
&\text{(ii)} \quad k_T^2 \frac{\partial}{\partial k_T^2} N_g(k_T^2) = \frac{\lambda_\chi(k_T^2)}{2\pi} \left( 8\pi^2 c_{gg} - \chi \Lambda^2 k_T^2 \right) \int_{k_T^2}^{Q_0^2} \frac{dk'}{k'} N_g(k'^2). \tag{59}
\end{align*}

On account of the \( k_T^2 \) dependence of \( \alpha_s \), Eq. (34), and \( \lambda_\chi \), Eq. (52), the corresponding solutions are obtained as

\begin{align*}
&\text{(i)} \quad N_g(k_T^2)|_{Q_0^2 \geq k_T^2 \geq \Lambda^2} = N_g(Q_0^2) \left( \frac{\ln(Q^2/\Lambda^2)}{\ln(k_T^2/\Lambda^2)} \right)^{-1/4} \exp \left[ \frac{2\sqrt{(C_A/\pi)b} \ln(Q^2/\Lambda^2)}{\ln(Q_0^2/\Lambda^2)} \right], \\
&\text{(ii)} \quad N_g(k_T^2)|_{Q_0^2 \geq k_T^2 \geq \Lambda^2} = N_g(Q_0^2) \exp \left[ - \frac{\rho \Lambda^2}{2k_T^2} \sqrt{1 + [1 + \ln(k_T^2/Q_0^2)]^2 - 2k_T^2/Q_0^2} \right]. \tag{60}
\end{align*}

In region (i) \( Q^2 \geq k_T^2 > Q_0^2 \), the multiplicity coincides with the QCD result [34], characterized by a rapid growth as the gap between the hard scale \( Q^2 \) and \( k_T^2 \) increases. On the other hand, in region (ii) \( Q_0^2 \geq k_T^2 > \Lambda^2 \), the multiplicity becomes strongly damped. The exponent is always negative so that the number of gluons rapidly decreases and vanishes at \( k_T^2 = 0 \), ensuring that no gluons and therefore no color fluctuations exist at distances \( R \geq \Lambda^{-1} \). This behavior is evident in Fig. 8, where \( N_g(k_T^2) \) is plotted versus \( \Lambda^2/k_T^2 \), starting from \( \Lambda^2/Q^2 \ll 1 \).

It must be emphasized that the perturbative evolution of gluons is cut off at \( Q_0^2 \), and in the transition region \( Q_0^2 > k_T^2 > \Lambda^2 \) the evolution is purely nonperturbative, although it is described here as an extension of the perturbative evolution above \( Q_0^2 \) and treated on the same footing.

**C. Flux tube configurations of gluons interacting with the mean field \( \chi \)**

In Secs. IIIA and IIB the evolution of the gluon configuration between the fragmenting \( q\bar{q} \) pair was analyzed in terms of the nonperturbative modification as a function of \( \lambda_\chi(k_T^2) = \xi_\chi^2/(4\pi) \). However, the coupling strength \( \lambda_\chi \) or \( \xi_\chi \) between the gluon field and the \( \chi \) field must be determined by the dynamics itself, since \( \xi_\chi \) is the Fourier transform of the \( \chi \)-dependent coupling function \( \xi(\chi) \) in Eq. (8).

The dynamics is governed by the coupled system of equations (19)–(21), which can now be solved numerically by utilizing the definition (36) together with the general solution for the gluon distribution given by (46) and (47). To do so, one obtains the expectation value of Eq. (20) by multiplying with the multigluon state vector \( | P \rangle \) and
the solution for \( \chi \) is known.

An interesting phenomenological application [21, 23, 42] is to calculate the string tension \( t \), which characterizes the linearly rising potential between the \( q \bar{q} \) pair due to the gluon interactions, usually obtained by fitting heavy quarkonium spectra [43] with a nonrelativistic potential of the form

\[
V_{q\bar{q}}(r) = -\frac{a}{r} + t r^2,
\]

where \( a = 4\alpha_s/3 \). Typical fit values for the string constant \( t \) range from 750 MeV/fm to 950 MeV/fm.

Here I shall estimate the string constant within the present approach on the basis of the equations of motion (19)–(21). Similar calculations have been done earlier in the framework of the static MIT bag model [44] and the Friedman-Lee soliton model [23, 42].

In the following I will consider the fragmentation of a heavy \( q \bar{q} \) pair within an adiabatic approximation. That is, a quasistatic treatment is employed which neglects the motion of the \( q \bar{q} \) pair and considers the instantaneous gluon configuration in between the pair. This should provide a reasonable approximation, because one can view the \( i \)th gluon as being emitted from the \( q \bar{q} \) pair plus gluons \( g_1, g_2, \ldots, g_{i-1} \), with the spatial coordinates of these "sources" being frozen during the emission of the gluon \( i \) [45]. In a space-time picture of the fragmentation of the \( q \bar{q} \) and its emitted gluons it is the change of the typical transverse momenta \( k_\perp \) or transverse separation \( r_\perp \propto k_\perp \) of gluons which governs the dynamical transition from short distance, unconfined regime to long distance, confined stage [2], because there must be a critical separation of color charges beyond which the total color is screened. In the present case, the role of this nonperturbative phenomenon is played by the \( \chi \) field. In the adiabatic approximation, there is no explicit dependence on the longitudinal variables here, because the separation in the transverse plane is independent of when during the cascade, or where along the jet axis, a gluon was produced [46].

Thus, within the adiabatic treatment, one may use the separation \( R_{q\bar{q}} \) of the receding \( q \bar{q} \) as a measure for the typical gluon transverse momenta \( k_\perp^2 \approx R_{q\bar{q}}^2 \). By minimizing the energy per unit length of this system, one obtains then for each gluon configuration at a given \( R_{q\bar{q}} \) the form of the \( \chi \) and the string tension \( t \). The total energy per unit length, the string tension \( t \), receives contributions from both the \( \chi \) field in the low energy regime and the gluon field in the high energy domain, which on account of the the trace anomaly (3) is given by

\[
t \equiv \frac{E}{R_{q\bar{q}}} = \int dA \left[ \frac{1}{2} |\nabla \chi|^2 + V(\chi) \right]
+ \int dA \kappa(\chi) \left( P \frac{\beta(\alpha_s)}{4\alpha_s} F_{\mu\nu} F^{\mu\nu} P \right).
\]

Here \( A \) is the cross-sectional area of the flux tube of the gluons between the \( q \bar{q} \) perpendicular to \( R_{q\bar{q}} \). In one-loop order the \( \beta \) function is \( \beta = -b_0 \alpha_s^2 \) with \( b = 33/(12\pi) \) for \( N_f = 0 \). Then, by using Eq. (36) to express the sec-
ond integral in terms of the gluon distribution \( g(x, k_T^2) \), assuming cylindrical symmetry along the \( R_{qq} \) axis, and minimizing \( t \) with respect to \( \chi \), one arrives at the following nonlinear integro-differential equation (\( r \) is the radial coordinate perpendicular to \( R_{qq} \)):

\[
- \left[ \frac{d^2}{dr^2} + \frac{1}{r} \frac{d}{dr} \right] \chi(r) + \frac{\partial V(\chi)}{\partial \chi} + \frac{(P^+)^2}{2} I_g(R_{qq}) \int dr \, r \, \kappa(\chi) = 0 ,
\]

where

\[
I_g(R_{qq}) = \int_{1/R_{qq}}^{(P^+)^2} d^2 k_\perp \alpha_s(k_\perp^2) \int_0^1 dx \, g(x, k_T^2) .
\]

(64)

In pulling \( I_g \) out of the \( r \) integral, it is assumed that the spatial distribution of gluons is approximately homogeneous. Equation (63) determines the energetically most favorable flux tube configuration. However, a physical meaningful flux tube solution has to satisfy the constraint that the system as a whole, \( q\bar{q} \) plus gluons, must form a global color singlet, implying that all of the color flux that originates from the \( q \) must be directed towards the \( \bar{q} \). In other words, the total color electric flux through a plane between the \( q \) and \( \bar{q} \) must equal the color charge \( Q_q = g_s T_3 \) on one of them [23, 42]. This translates into the requirement that the gluons in the flux tube stretched between \( q \) and \( \bar{q} \) with certain \( R_{qq} \) carry a total color charge squared that is equal to \( Q_q^2 \), the one of \( q\bar{q} \). Define

\[
\phi_g = \frac{(P^+)^2}{A} \int d^2 r \, J_g(R_{qq}) ,
\]

where \( A \) is the cross-sectional area of the flux tube and

\[
J_g(R_{qq}) = \int_{1/R_{qq}}^{(P^+)^2} d^2 k_\perp \int_0^1 dx \, g(x, k_T^2) .
\]

(66)

is the total number of gluons radiated from the initial point of \( q\bar{q} \) production up to \( R_{qq} \). Then the above constraint then reads

\[
\phi_g = \frac{1}{4} Q_q^2 = \left( g_s^2 T_3 \cdot T_3 \right) = \frac{16\pi}{3} \alpha_s(k_T^2) \bigg|_{k_T^2=R_{qq}^{-2}} .
\]

(67)

Combining Eqs. (63)–(67), one arrives at

\[
- \left[ \frac{d^2}{dr^2} + \frac{1}{r} \frac{d}{dr} \right] \chi(r) + \frac{\partial V(\chi)}{\partial \chi} + \frac{8\pi}{3} b \alpha_s(R_{qq}^{-2}) \frac{I_g(R_{qq})}{J_g(R_{qq})} \int dr \, r \, \kappa(\chi) = 0 ,
\]

(68)

which is now independent of the overall boost momentum \((P^+)\), and thus of the initial hard scale \( Q^2 = (P^+)^2 \), as it should be.

Solving Eq. (68) numerically [47], subject to the boundary conditions \( \chi'(0) = 0 \) and \( \chi(\infty) = x_0 \), yields the solutions for \( t, \chi \), and \( \kappa(\chi) \) shown in Fig. 9. The reasonable parameter values [17] \( x_0 = f_\pi \) and bag constant \( B = (150 \text{ MeV})^4 \) were chosen for \( V(\chi) \), Eq. (14), and the coupling function \( \kappa \) was taken of the form (11). One sees that with increasing separation \( R_{qq} \) of \( q \) and \( \bar{q} \), the gluons first multiply which results in a growing string tension, but then gluon condensation sets in, yielding a saturating behavior of \( t \) with the string constant approaching \( t \approx 1 \text{ GeV/fm} \) [Fig. 9(a)]. For \( R_{qq} \approx 1 \text{ fm} \) the gluon field is completely confined within a flux tube of radius \( r \approx 1 \text{ fm} \) [Fig. 9(b)]. For comparison, a simple estimate within the MIT bag model [44] gives

![Fig. 9](image1)

**Fig. 9.** (a) String tension \( t \) versus separation \( R_{qq} \) of the \( q\bar{q} \) pair, and (b) the solutions for \( \chi \) and \( \kappa \) at \( R_{qq} = 1 \text{ fm} \) versus \( r \) which is the radial coordinate perpendicular to \( R_{qq} \) (\( \chi_0 = f_\pi \) and \( B^{1/4} = 150 \text{ MeV} \)).

![Fig. 10](image2)

**Fig. 10.** (a) Form of the potential \( V(\chi(r)) \) and (b) the effective squared mass \( M^2(\chi(r)) \) of the \( \chi \) field, both at \( R_{qq} = 1 \text{ fm} \) (\( \chi_0 = f_\pi \) and \( B^{1/4} = 150 \text{ MeV} \)).
t = 910 MeV/fm, but a rather large tube radius of 1.6 fm. Detailed calculations within the soliton model [23] gave qualitatively similar results. Finally, Fig. 10 shows in correspondence to Fig. 9(b) the form of the potential $V(x) = V(x, U)|_{n_{c}=0}$, defined in Eq. (14), and the effective squared mass $M^2(x) = d^2V(x)/dx^2$ for the same parameter values as above.

IV. SUMMARY AND OUTLOOK

The effective QCD field theory approach presented here to describe the dynamics of high energy partons in the presence of a collective confinement mechanism provides a framework that has the potential to be developed towards a systematic description of the hadronization mechanism. The corresponding effective action has been constructed such that it (i) incorporates both parton and hadron degrees of freedom, (ii) recovers the exact QCD (Yang-Mills) action with its symmetry properties at short space-time distances, (iii) merges into an effective low energy description of hadronic degrees of freedom at large distances, and (iv) allows for a dynamical description of parton-hadron conversion on the basis of the resulting equations of motion.

As an exemplary demonstration, the approach was applied to the evolution of a fragmenting $gq$ pair with its generated gluon distribution, starting from a large hard scale $Q^2$ all the way down to $\Lambda^2$. The transformation of the initially high virtual gluons to a gluon condensate field $\chi$ was studied in terms of the coupled evolution of the gluon distribution and the mean field $\chi$. The solution of the equations of motion yields color flux tube configurations with an associated energy per unit area (string tension) of about 1 GeV/fm, consistent with the common estimates.

In perspective, important points to be addressed in the future are the following:

(i) The establishment of the relation with the exact renormalization group equation for the effective action as derived by Reuter and Wetterich [5] is desirable. This would allow one to quantify the effect of consecutively integrating out all quantum fluctuations of gluons and quarks with momenta larger than some infrared cutoff scale $Q_0$, the variation of which determines the confinement dynamics.

(ii) With the inclusion of quark degrees of freedom and possibly quantum fluctuations of the $\chi$ and $U$ fields, one could calculate, e.g., the mass spectrum of glueball and meson excitations as physical hadrons. This would provide a complete description from a physical initial state, via a not directly observable deconfined partonic stage, up to the formation of observable hadronic excitations.

(iii) Ultimately one would like to address the microscopic dynamics in full six-dimensional phase space [48], with explicit inclusion of the color degrees of freedom and the local color structure. This could be realized in a transport theoretical formulation similar as in Ref. [49], in which the partons propagate with a modified propagator that embodies the effects of the mean field $\chi$ in the effective mass. As the confining field becomes significant the effective mass increases and asymptotically becomes infinite so that the propagation of color fluctuations ceases.

(iv) The possible applications are manifold. One particular interest is the expected (non)equilibrium QCD phase transition in high energy systems as in heavy ion collisions or the early Universe, an issue which could be addressed along the lines of Campbell, Ellis, and Olive [17] in combination with the space-time evolution of the multiparton system [48] in the presence of the collective field.

ACKNOWLEDGMENTS

I thank J. Ellis, H.-T. Elze, B. Müller, and G. Veneziano for valuable suggestions. Thanks also to L. Wilets and W. Hofer for providing the computer code for the flux tube calculation.

APPENDIX A

For completeness a “derivation” of the evolution equation (26) is given in the spirit of Lipatov [50]. The full propagator of a single gluon of momentum $k$ may be represented as

$$D_{\mu\nu}(k) = \frac{d_{\mu\nu}(k)}{k^2 \left[ 1 + \Pi(k^2) \right]} \equiv \frac{D^0_{\mu\nu}(k)}{1 + \Pi(k^2)}, \quad (A1)$$

where $D^0_{\mu\nu} = d_{\mu\nu}/k^2$ is the free propagator, and, with the choice of gauge for the gluon fields $\eta \cdot A = 0$,

$$d_{\mu\nu}(k) = g_{\mu\nu} - \frac{k_\mu \eta_\nu + k_\nu \eta_\mu}{k \cdot \eta}, \quad d_{\mu\nu}(k) = 2, \quad (A2)$$

and $k^2 d_{\mu\nu}(k)|_{k^2 = 0} = 0$ guarantees that only two physical (transverse) gluon polarizations propagate on mass shell.

The self-energy part

$$\Pi(k^2) = \Pi_{g \rightarrow g}(k^2) + \Pi_{g \rightarrow \chi}(k^2) \quad (A3)$$

contains both the gluon self-interactions and the “medium” corrections due to the coupling to the confining background field $\chi$. Expanding $\Pi_{g \rightarrow g}$ and $\Pi_{g \rightarrow \chi}$ in powers of the squared couplings $g_1^2$ and $\xi^2$, respectively, the contribution to one-loop order is determined by the total gluon “decay” probability, i.e., the probability of losing a gluon out of a momentum space element between $k^2$ and $k^2 + dk^2$:

$$w_g(k^2) = \frac{\partial}{\partial \ln(k^2/\Lambda^2)} \left[ \Pi_{g \rightarrow g}(k^2) + \Pi_{g \rightarrow \chi}(k^2) \right]|_{k^2 = k^2} \equiv w_{g \rightarrow g} + w_{g \rightarrow \chi}. \quad (A4)$$

Here, $w_{g \rightarrow g}$ and $w_{g \rightarrow \chi}$ are the inclusive probabilities for a gluon to emit (absorb) another gluon, due to the self interaction, and the interaction with the $\chi$ field, respectively, corresponding to the diagrams in Fig. 4:
\[ w_{g\to g}(k^2) = \int_0^1 dx \int_x^1 dx' \left[ w_{g\to gg}(x', x, k^2) + w_{gg\to g}(x', x, k^2) \right], \]

\[ w_{g\to \chi}(k^2) = \int_0^1 dx \int_x^1 dx' \left[ w_{g\to \chi}(x', x, k^2) + w_{gg\to \chi}(x', x, k^2) \right]. \tag{A5} \]

The individual contributions in square brackets \( w(x_1, x_2, k^2) \) can be obtained in the standard fashion \([51, 52]\) by evaluating the cross-section ratios (cf. Appendix B)

\[ \frac{k^2}{\sigma^{(0)}} \frac{d\sigma^{(1)}}{dzdk^2} = \frac{g^2}{8\pi^2} \gamma_{a\to bc}(z), \tag{A6} \]

where \( g \) denotes the appropriate coupling for the process under consideration (here \( g = g_a \) or \( g = \xi_x \)), \( \sigma^{(0)} \) is the Born cross section for the production of a gluon \( a \), and \( \sigma^{(1)} \) represents the first order correction associated with the “decay” \( a \to bc \).

For the process \( g \to gg \) and its reversal \( gg \to g \), the probability distributions (33) are well known \([51, 39]\). Assigning the momentum fractions as \( x_1 \to x_2, (x_2 - x_1) \to x_2 \) for \( g \to gg \) and \( x_1, (x_2 - x_1) \to x_2 \) for \( gg \to g \), one has

\[ w_{g\to gg}(x_1, x_2, k^2) = \frac{\alpha_s(k^2)}{2\pi} \gamma_{g\to gg} \left( \frac{x_2}{x_1} \right), \]

\[ w_{gg\to g}(x_1, x_2, k^2) = \frac{\alpha_s(k^2)}{2\pi} \left[ \frac{8\pi c_{gg\to g}}{k^2} \right] \times \frac{x_1(x_2 - x_1)}{x_2^2} \gamma_{gg\to g} \left( \frac{x_1}{x_2} \right), \tag{A7} \]

where in the second expression the factors in square brackets arise from the difference of phase space and flux factors for fusions compared to branchings. The color factor is \( c_{gg\to g} = 1/8 \) and

\[ \gamma_{g\to gg}(z) = 2\, C_A \left( z(1 - z) + \frac{z}{1 - z} + \frac{1 - z}{z} \right), \tag{A8} \]

where \( C_A = N_c = 3 \), and \( z \) is the fraction of \( x \) values of daughter to mother gluons.

The new, additional processes are the friction process \( g \to g\chi \), corresponding to energy-momentum transfer from gluons to the \( \chi \) field, and the fusion process \( gg \to \chi \), by which two gluons couple color neutral to the \( \chi \) field and “annihilate.” As outlined in Appendix B, one arrives at (with the assignment \( x_1 \to x_2, (x_2 - x_1) \to x_2 \) for \( g \to g\chi \) and \( x_1, (x_2 - x_1) \to x_2 \) for \( gg \to \chi \))

\[ w_{g\to g\chi}(x_1, x_2, k^2) = \frac{\lambda_\chi(k^2)}{2\pi} \gamma_{g\to g\chi} \left( \frac{x_2}{x_1} \right), \]

\[ w_{gg\to \chi}(x_1, x_2, k^2) = \frac{\lambda_\chi(k^2)}{2\pi} \left[ \frac{8\pi c_{gg\to g}\Lambda^2}{k^2} \right] \times \frac{x_1(x_2 - x_1)}{x_2^2} \gamma_{gg\to \chi} \left( \frac{x_1}{x_2} \right), \tag{A9} \]

where \( c_{gg\to \chi} = 1/8 \) and

\[ \gamma_{g\to g\chi}(z) = \frac{1}{4} \left( \frac{1 + z^2}{1 - z} \right), \]

\[ \gamma_{gg\to \chi}(z) = 8 \left( z^2 - z + \frac{1}{2} \right). \tag{A10} \]

The total interaction probability \( w_g \), Eq. (A4), determines via the unitarity condition (30) the Sudakov form factor \( F_g \),

\[ F_g(Q^2, k^2) = \exp \left[ -\int_{k^2}^{Q^2} \frac{d\zeta}{k^2} w_g(\zeta^2) \right], \tag{A11} \]

which is the probability that a gluon does not at all interact (i.e., emit or absorb other gluons) while degrading its virtuality from \( Q^2 \) to \( k^2 \).

The self-energy part (A3) is now readily evaluated on the basis of Eq. (A4), and inserted in the representation (A1), one obtains the single gluon propagator at one-loop order:

\[ D_{\mu\nu}(k) = D_{\mu\nu}^0(k) \left[ 1 + \int_{k^2}^{Q^2} \frac{dk'}{k'^2} \times \int_x^1 \frac{dz'}{z'} w(z', x, k^2) \right]. \tag{A12} \]

The corresponding “jet calculus” [28] Green’s function

\[ \lambda_\chi(k^2) = \ldots \]

\[ \text{Since the conversion of partons into hadrons in the process of fragmentation is an irreversible process, the spontaneous production of gluons by the \( \chi \) field, \( \chi \to gg \), as well as the energy transfer from the \( \chi \) field to the gluons, \( g\chi \to g \), is omitted. These latter interactions would counteract the transition, which certainly is possible in the sense of local fluctuations, but globally, and in the average, the parton-hadron conversion is a one-way process in the present context.} \]
\[ D_g(x, k^2; x_0, Q^2) \] of Eq. (26) describes how a system of gluons evolves in the variable \( z \) and the virtuality \( k^2 \) through the gluon self-interactions and in the presence of the confining background field \( \chi \). It is given by the convolution of the single gluon propagator (A1) with the gluon distribution function \( g(x, k^2) \). Defining

\[ D_g(x, k^2; x_0, Q^2) \equiv g_{\mu \nu} D^{\mu \nu}(k) \otimes g(x, k^2), \tag{A13} \]

the self-consistent iteration of one-loop contributions to all orders within the LLA gives the evolution equation for the gluon distribution with respect to the variables \( x \) and \( k^2 \):

\[
\begin{align*}
\frac{k^2}{\partial \frac{k^2}{\partial x}} g(x, k^2) &\equiv \frac{k^2}{\partial \frac{k^2}{\partial x}} D_g(x, k^2; x_0, Q^2) \\
&= + \frac{\alpha_s(k^2)}{2 \pi} \left\{ \int_0^1 \frac{dx'}{x'} g(x', k^2) \gamma_{g \to gg} \left( \frac{x}{x'} \right) - \frac{1}{2} \frac{g(x, k^2)}{2 \pi} \right\} d_g - \frac{1}{2} \frac{g(x, k^2)}{2 \pi} \int_0^1 \frac{dx'}{x'} g(x', k^2) \Gamma_{gg \to g} \left( \frac{x}{x'}, x + x' \right) \\
&\quad - \frac{1}{2} \frac{g(x, k^2)}{2 \pi} \left\{ \int_0^1 \frac{dx'}{x'} g(x', k^2) \Gamma_{gg \to g}(x - x', x', x) \right\} \\
&\quad + \frac{\lambda_s(k^2)}{2 \pi} \left\{ \int_0^1 \frac{dx'}{x'} g(x', k^2) \gamma_{g \to g\chi} \left( \frac{x}{x'} \right) - \frac{g(x, k^2)}{2 \pi} \int_0^1 \frac{dx}{x} g_{\gamma \to g\chi} \left( \frac{x}{x} \right) \right\} \\
&\quad - \frac{\lambda_s(k^2)}{2 \pi} \left\{ \int_0^1 \frac{dx'}{x'} g(x', k^2) \Gamma_{gg \to g\chi}(x, x', x + x') \right\}, \tag{A14}
\end{align*}
\]

where the factor 1/2 in the first (third) term arises from the indistinguishability of the two gluons emerging from (coming in) the branching (fusion) vertex. The function \( g^{(2)}(x_1, x_2, k^2) \) denotes the two-gluon density, and the gluon fusion functions \( \Gamma \) are defined in accord with (A7) and (A9) as

\[
\Gamma_{12 \to 3}(x_1, x_2, x_3) = \Gamma_{12 \to 3} \left( \frac{x_1 x_2}{x_3} \right) \gamma_{3 \to 12} \left( \frac{x_1}{x_3} \right) = \Gamma_{12 \to 3} \left( \frac{x_1 x_2}{x_3} \right) \gamma_{3 \to 21} \left( \frac{x_2}{x_3} \right) \tag{A15}
\]

with \( x_3 = x_1 + x_2 \). Changing to variables \((x, x_1, k^2) \to (x, k^2, x_1) \) and using (A15), one immediately arrives at Eq. (31).

**APPENDIX B**

Here I will outline the explicit calculation of the interaction probability densities \( \gamma_{g \to g\chi} \) and \( \Gamma_{gg \to g} \) that appear in the evolution equation (A14) or (38) in addition to the usual probability densities \( \gamma_{g \to gg} \) and \( \Gamma_{gg \to g} \). Notice that the vertex corresponding to three gluons coupling to the \( \chi \) field is unphysical and therefore to be excluded, because \( \chi \) is required to be a color singlet field. On the other hand, the coupling of four gluons to \( \chi \) is possible; however, in the LLA such diagrams are kinematically suppressed and can be neglected [2].

Let \( \sigma^{(N)} \) denote the spin- and color-averaged cross section for the production of a gluon at order \( N \) in perturbation theory. The probability distribution \( \gamma_{a \to bc} \) in the variable \( z = x_b/x_a \) for the emission of a gluon \( b \) in the process \( a \to bc \) is given by the ratio of cross sections,

\[
\frac{1}{\sigma^{(0)}} \frac{d\sigma^{(1)}}{dz} = \frac{g^2}{8 \pi^2} \gamma_{a \to bc}(z) \frac{dk^2}{k^2}, \tag{B1}
\]

where \( g \) is the appropriate coupling of the process, \( \sigma^{(0)} \) is the lowest order cross section for the production of a gluon \( a \), and \( \sigma^{(1)} \) represents the first order correction associated with the “decay” \( a \to bc \). The vertex function associated with the general \( gg\chi \) coupling is easily obtained from the interaction Lagrangian \( \mathcal{L}[\psi, A, \chi] \), Eq. (8), as

\[
V^{a b}(k_1, k_2, k) = -\tilde{\xi}_{k}(k) \delta^{ab} \left( k_1 \cdot k_2 \right) g_{\mu \nu} \tag{B2}
\]

\[
= (1 - a) \left( k_1, k_2 \right),
\]

where \( \tilde{\xi}_k(k^2) \) denotes the Fourier transform of \( \xi_k(\chi) \) in coordinate space, \( k_1, k_2 \) are the gluon momenta, and the convention is that all four-momenta are directed into the vertex. The process \( g \to g\chi \) gives then (setting \( a = 1 \))

\[
\sigma^{(1)}(k_1^2) = \int \frac{d^3k}{(2\pi)^32k_0} \frac{2}{(k_1 \cdot k)^2} \sigma^{(0)}(k_1^2) |\mathcal{M}|^2, \tag{B3}
\]

where

\[
|\mathcal{M}|^2 = \frac{1}{16} \sum_{a, a', b, b', s_1, s_2} \sum_{V_{\mu \nu}}^V \sum_{V_{\mu' \nu'}}^V \times \epsilon_{\mu}^b(s_1) \epsilon_{\mu'}^{a'}(s_1) \epsilon_{\nu}^a(s_2) \epsilon_{\nu'}^{a'}(s_2), \tag{B4}
\]

where the factor 1/16 in front results from the averaging
over initial two transverse polarizations and eight color
degrees, and it is summed over final color and spin polar-
izations $s_i$. The sum over gluon polarizations $s_1, s_2$
must be performed over transverse polarizations only. This is
achieved by the projection

$$\sum_{s_i} e^{\mu}(s_i) e^{\nu}(s_i) = -g^{\mu\nu} + \frac{k^\mu k^\nu + k^\nu k^\mu}{(k \cdot k_1)} - \frac{k^\mu k^\nu}{(k \cdot k_1)^2} .$$

(B5)

Assigning the momenta $k^\mu = (k^+, k^-, k_\perp)$ of incoming
(outgoing) gluon $k_1$ ($k_2$) and the momentum $k$ trans-
ferred to the $\chi$ field as

$$k_1 = (k^+_1, 0, 0, k_\perp) ,$$

$$k_2 = \left( 1 - z , k^+_1 \left( 1 - z \right)^{-1} , -k_\perp, 0 \right) ,$$

$$k = \left( z k^+_1 , z k^+_1 , z k_\perp, k_\perp \right) ,$$

(B6)

and carrying out the appropriate change of integration
variables, the result is

$$s^{(1)}(k^2) = s^{(0)}(k^2) \frac{\hat{x}^2}{8\pi^2} \int \frac{k^2}{k^2_1} \frac{dk^2}{k^2_1} \int dz \left[ \frac{1}{4} \left( 1 - z \right) + \frac{z}{1 - z} \right] .$$

(B7)

Hence, one can read off

$$\gamma_{g \rightarrow g \chi}(z) = \frac{k^2_1}{s^{(0)}} \frac{d\sigma^{(1)}}{dz dk^2_1} = \frac{1}{4} \left( 1 + \frac{z^2}{1 - z} \right) .$$

(B8)

In complete analogous manner the process $gg \rightarrow \chi$ can
be calculated. The procedure is to evaluate $\chi \rightarrow gg$,
with incoming momentum $k$ and the outgoing momenta
$k_1$ and $k_2$. Using the formula (A15) one obtains the two-
gluon fusion function for the reverse process $gg \rightarrow \chi$. The result is

$$\Gamma_{gg \rightarrow \chi}(x_1, x_2, x_3) = c_{gg \rightarrow \chi} \frac{x_1 x_2}{x_3^2} \gamma_{g \rightarrow g}(x_1) \gamma_{g \rightarrow g}(x_3) ,$$

(B9)

$$\gamma_{g \rightarrow g}(z) = 8 \left( z^2 - z + \frac{1}{2} \right) .$$
