We present lattice calculations of kaon matrix elements with domain wall fermions. Using lattices with $6/g^2 = 5.85, 6.0, \text{ and } 6.3$, we estimate $B_K(\mu \approx 2 \text{ GeV}) = 0.628(47)$ in quenched QCD which is consistent with previous calculations. At $6/g^2 = 6.0$ and 5.85 we find the ratio $f_K/m_\rho$ in agreement with the experimental value, within errors. These results support expectations that $O(a)$ errors are exponentially suppressed in low energy ($E \ll a^{-1}$) observables, and indicate that domain wall fermions have good scaling behavior at relatively strong couplings. We also demonstrate that the axial current numerically satisfies the lattice analog of the usual continuum axial Ward identity.

While lattice gauge theory has made significant progress in addressing the outstanding challenge of calculating hadronic observables from first principles, a basic feature of the strong interactions has been missing in these calculations, the $\text{SU}(N_f)_L \times \text{SU}(N_f)_R$ chiral flavor symmetry of the light quarks which is broken explicitly by present lattice discretizations of continuum QCD. We recently reported [1] on calculations using a new discretization for simulations of QCD, domain wall fermions (DWF) [2,3], which preserve chiral symmetry on the lattice in the limit of an infinite extra 5th dimension. There it was demonstrated that DWF exhibit remarkable chiral behavior [1] even at relatively large lattice spacing and modest extent of the fifth dimension. Here we give further results using DWF which are of direct phenomenological interest.

In addition to retaining chiral symmetry, DWF are also “improved” in another important
way. In the limit that the number of sites in the extra dimension, \( N_s \), goes to infinity, the leading discretization error in the effective four dimensional action for the light degrees of freedom goes like \( O(a^2) \), unlike the case for ordinary Wilson fermions, for which the errors are \( O(a) \), \( a \) being the lattice spacing. This theoretical dependence is deduced from the fact that the only operators available to cancel \( O(a) \) errors in the effective action are not chirally symmetric; thus no \( O(a) \) errors exist in the low energy theory. For finite \( N_s \), \( O(a) \) corrections are expected to be exponentially suppressed with the size of the extra fifth dimension. Our calculations for \( B_K \) show a weak dependence on \( a \) that is easily fit to an \( a^2 \) ansatz. At \( \beta = 6.0 (\beta \equiv 6/g^2) \) the lattice spacings determined from \( m_\rho \) and \( f_\pi \) agree within less than five percent. This improved scaling behavior is plausible in light of the fact that DWF retain an important continuum symmetry at non-zero lattice spacing.

As in our previous paper, we use the boundary fermion variant of DWF \[2\] developed by Shamir \[3\]. The DWF action is essentially a five dimensional analog of the ordinary Wilson fermion action with two key differences: (1) the relative sign between the Wilson term and the (five dimensional) Dirac mass, \( M \), is opposite to the usual convention. This leads to the appearance of massless chiral modes on the boundaries of the fifth dimension, a left handed fermion on one wall and a right handed one on the other. (2) The layers \( s = 0 \) and \( s = N_s - 1 \) (\( s \) denotes the coordinate in the extra dimension) are coupled with strength \(-m\) (\( m \geq 0 \)). Neglecting exponentially small corrections, in Ref. \[3\] it was shown that the parameter \( m \) is (proportional to) the mass of the light four dimensional quark which is assembled from the two chiral modes, \( m_q = mM(2 - M) \). The chiral limit is \( N_s \rightarrow \infty \) and \( m \rightarrow 0 \), which requires no fine tuning unlike ordinary Wilson fermions.

Recently the exponentially small corrections to the quark mass have been given at tree level \[4\], \( m_q = M(2 - M)(m + \{1 - M + O(p^2)\}^{N_s}) \). In the presence of interactions \( M \) is renormalized additively just like ordinary Wilson fermions which also acquire a “mass term” proportional to \( p^2 \). Perturbatively at one loop the main effect of the interactions is the replacement \( M \rightarrow M + g^2 \Sigma(p) \) \[3\] where \( \Sigma(p) \) is the quark self-energy. Thus the chiral limit still holds with the replacement \((1 - M)^{N_s} \rightarrow (M_c - M)^{N_s} \). This is analogous to the
renormalization of the critical hopping parameter from its tree level value of 1/8 in the case of ordinary Wilson fermions. Of course, the crucial difference is that for DWF the additive corrections are exponentially suppressed. In our original study we found $M_c \approx 1.7$ for non-perturbative couplings corresponding to quenched simulations at $\beta \sim 6.0$, which also agrees roughly with a simple mean field argument [1].

For QCD, the DWF are gauged in the ordinary four dimensions only, and the left and right handed modes couple equally to the gauge field. Thus the five dimensional theory gives rise to a low energy effective theory ($E << a^{-1}$) describing interacting vector quarks in four dimensions whose right and left handed components are localized around $s = 0$ and $s = N_s - 1$, respectively.

In Ref. [5] it was shown that operators constructed from the quark fields formed by the chiral modes on each wall satisfy the following four dimensional chiral Ward identities (CWI).

\[
\Delta_\mu \left( A_\mu^a(x)O(y_1, y_2, ...) \right) = 2m \left( J^a_5(x)O(y_1, y_2, ...) \right) + 2 \left( J^a_{5q}(x)O(y_1, y_2, ...) \right) + i \left( \delta^a_\mu O(y_1, y_2, ...) \right),
\]

which result from demanding invariance of $\left< O(y_1, y_2, ...) \right>$ under an infinitesimal axial transformation $\delta^a_\mu$. Here $A_\mu^a$ is the four dimensional partially conserved axial current (PCAC) constructed from a sum of five dimensional fields over all slices in the extra dimension [5]. The operators $O(y_1, y_2, ...)$ and the pseudoscalar density $J^a_5(x)$ are constructed from four dimensional quark fields using the chiral modes on each boundary,

\[
g(x) = \frac{1 + \gamma^5}{2} \psi(x, 0) + \frac{1 - \gamma^5}{2} \psi(x, N_s - 1),
\]

\[
\bar{q}(x) = \bar{\psi}(x, N_s - 1) \frac{1 + \gamma^5}{2} + \bar{\psi}(x, 0) \frac{1 - \gamma^5}{2}.
\]

In Eq. 1, $J^a_{5q}$ is an anomalous pseudoscalar density that results from the non-invariance of the action under the axial transformation for finite $N_s$. For flavor non-singlet currents, this contribution to the r.h.s. of Eq. 1 vanishes identically in the limit $N_s \to \infty$ [5], and we are left with the continuum-like relations. Below we demonstrate explicitly that at $\beta = 6.0$.
Eq. 1 is satisfied for the usual PCAC Ward identity, \( O(y_1, y_2, \ldots) = J_5 \), and the anomalous contribution is small for \( N_s = 10 \) and reduces further by more than a factor of 2.5 as \( N_s \) is increased to 14.

To obtain \( B_K \) we need the matrix element of the \( \Delta s = 2 \) four quark operator that governs \( K - \bar{K} \) mixing, \( O(\mu)_{LL} = [\bar{s}\gamma_\nu(1 - \gamma_5)d]^2 \), which depends on the energy scale \( \mu \). On the lattice and using DWF, \( O_{LL} \) is a simple transcription of the above using the quark fields in Eq. 2. Sandwiching \( O_{LL} \) between \( K \) and \( \bar{K} \) states and taking the ratio with its value in vacuum saturation yields \( B_K \).

**TABLE I.** Summary of simulation parameters. “size” is the number of spatial sites times the temporal extent times \( N_s \). \( M \) is the five dimensional Dirac fermion mass, and \( m \) is the coupling between layers \( s = 0 \) and \( N_s - 1 \). The number in parentheses is the number of configurations used at each value of \( m \).

In order to investigate the continuum limit of quenched QCD with DWF, we have carried out simulations at gauge couplings \( \beta = 5.85, 6.0, \) and 6.3. The simulation parameters are summarized in Table I. The number of configurations in our study is rather small, and we have made no attempt to estimate finite (four dimensional) volume systematic errors. These deficiencies will, of course, be addressed in future works. The lattices correspond to \( (1.5 \text{ fm})^3 \) for \( \beta = 6.0 \) and 6.3 and \( (2.1 \text{ fm})^3 \) for 5.85, which from previous lattice studies may result in a deviation of a few percent from the infinite volume case. We have begun to address systematic corrections due to finite \( N_s \). All of the correlation functions discussed below were calculated in the lattice Landau gauge which was chosen for convenience, in principle any gauge will do.

We begin by discussing the numerical investigation of Eq. 1 for \( O = J_5 \). First, Eq. 1
is satisfied exactly on any configuration since it is derived from the corresponding operator identity. We checked this explicitly in our simulations. In the asymptotic large time limit we get

\[2 \sinh \left(\frac{am_\pi}{2}\right) \langle A_\mu | \pi \rangle / \langle J_5 | \pi \rangle = 2m + 2 \langle J_5q | \pi \rangle / \langle J_5 | \pi \rangle,\]

which goes over to the continuum relation for \( am_\pi \ll 1 \) and \( N_s \to \infty \). At \( \beta = 6.0 \) and \( N_s = 10 \) we find the l.h.s. of Eq. 3 to be 0.1578(2) and 0.1083(3) for \( m = 0.075 \) and 0.05, respectively. The anomalous contributions for these two masses are \( 2 \times (0.00385(5) \) and 0.00408(12)), which appears to be roughly constant with \( m \). Increasing \( N_s \) to 14 at \( m = 0.05 \), the anomalous contribution falls to \( (2 \times) 0.00152(8) \) while the l.h.s. is 0.1026(6), which shows that increasing \( N_s \) really does take us towards the chiral limit.

While we have not investigated the CWI for \( O_{LL} \), the matrix element \( \langle K^0 | O_{LL} | \bar{K}^0 \rangle \) vanishes linearly with \( m \) in the chiral limit as required by chiral perturbation theory and shown in Fig. 1. This indicates that the anomalous term in Eq. 1 for \( O_{LL} \) is highly suppressed. At \( \beta = 5.85 \) the two data points extrapolate linearly to -0.0005(100) at \( m = 0 \). At \( \beta = 6.0 \) the three data points extrapolate to -0.004(9) with a \( \chi^2 \) per degree of freedom of 0.2 for a non-covariant fit. We do not have enough data to perform a covariant fit. At \( \beta = 6.3 \), the two points extrapolate to 0.05(3). This slight overshoot is not unexpected since the values of \( m \) used are for rather heavy quarks. In our initial study we found a similar behavior [1], and as the quark mass was lowered, the required linear behavior set in. Since we do not have a smaller mass at this coupling, there will be a small systematic increase in \( B_K \) since the fit will overestimate the matrix element at the strange quark mass. All of the above results are for \( N_s = 10 \) except at \( \beta = 5.85 \) where \( N_s = 14 \) was used for reasons explained below.

Fig. 2 shows \( B_K \) as a function of \( am_\rho \), or equivalently the lattice spacing. \( B_K \) is estimated at each coupling from a linear fit of the degenerate quark data. The fit is then evaluated at one-half the value of \( m \) corresponding to the strange quark as determined from a fit to the pseudoscalar mass squared (see below). \( am_\rho \) is determined from a simple jackknife average.
of the effective mass over a suitable plateau. The results for $B_K$ depend weakly on $\beta$, and are well fit to a pure quadratic in $a$. Using this fit, we find $B_K(\mu = a^{-1}) = 0.628(47)$ in the continuum limit with a confidence level of 0.39. This result is already consistent with the previous Kogut-Susskind result [6,7] and a recent Wilson quark result [8] using CWI's similar to Eq. 1 to enforce the proper chiral behavior of $O_{LL}$ for Wilson quarks. We note that the data can be fit to a linear function of the lattice spacing as well, which yields $B_K(\mu = a^{-1}) = 0.617(80)$, though we emphasize again that linear corrections are expected to be highly suppressed on theoretical grounds. More importantly, there is no evidence for $O(a)$ corrections in Fig. 1. Similarly, the denominator in $B_K$, $\langle \bar{K}|O_{LL}|K\rangle_{VS}$, exhibits the correct chiral behavior. Above, the notation $B_K(\mu = a^{-1})$ simply means the uncorrected lattice data have been used to perform the extrapolation; i.e., our result does not include the perturbative running of $B_K$ at each lattice spacing to a common energy scale. This requires a perturbative calculation to determine the renormalization of $O_{LL}$, which has not yet been done. The energy scale at $\beta = 6.0$, as determined by the inverse lattice spacing, is roughly 2 GeV. Since the dependence on $a$ is already mild, this should not have a significant impact on our $a = 0$ estimate. We also note that the coefficient of the quadratic term in our fit is $0.12(23)$, or zero within errors. Also, from our previous work [1] which did not give a value for $B_K$, we find $B_K(\mu = a^{-1}) = 0.617(4)$ on a set of 20 Kogut-Susskind lattices with $m_{KS} = 0.01$ and $\beta = 5.7$ [9] and the same five dimensional lattice volume as the point at $\beta = 6.0$. The energy scale is nearly that of $\beta = 6.0$, quenched. This partially unquenched result indicates that the error from quenching may be small, as was found for $B_K$ using Kogut-Susskind quarks [10,11].

At $\beta = 6.0$, we have also calculated $B_K$ using the partially conserved axial current $A^a_\mu(x)$ (and the analogous vector current) at $m = 0.05$ and 0.075. This point split conserved current requires explicit factors of the gauge links to be gauge invariant. Alternatively a gauge non-invariant operator may be defined by omitting the links; the two definitions become equivalent in the continuum limit. Results for the gauge non-invariant operators agree within small statistical errors with those for operators constructed from Eq. 2. The
results for the gauge invariant operators are somewhat larger: \( B_K^{inv}(\mu = a^{-1}) = 0.872(22) \) and 0.926(19) at \( m = 0.05 \) and 0.075, respectively. A similar situation holds in the Kogut-Susskind case where it was shown that the gauge invariant operators receive appreciable perturbative corrections which bring the two results into agreement [10].

Using Eq. 3, neglecting the anomalous contribution, and using the definition of the decay constant \( f_{PmP} \equiv \langle 0|A_{S0}|P\rangle \), we can determine the pseudoscalar decay constant from the measurement of \( \langle 0|J_5^a|P\rangle \). Performing simultaneous covariant fits to the wall-point and wall-wall correlators of \( J_5 \) yields the matrix element. At \( \beta = 5.85 \) and 6.0 each fit has a good confidence level (CL \( \approx 0.7 \)). The results are shown in Fig. 3. Proceeding as before with \( B_K \), we find \( f_K = 159(14) \) MeV and 164(12) MeV for \( \beta = 6.0 \) and 5.85, respectively.

The errors are statistical and do not include the error in the lattice spacing determination from \( am_\rho \). The central values agree with experiment, \( f_{K+} = 160 \) MeV. The lattice spacing determinations from \( am_\rho \) give \( a^{-1} = 1.53(27), 2.09(21), \) and 3.20(81) GeV at \( \beta = 5.85, 6.0, \) and 6.3, respectively. These are similar to Wilson and Kogut-Susskind lattice spacings for similar quenched lattices. Alternatively, we may form the dimensionless ratio \( f_K/m_\rho \). We find for \( \beta = 5.85 \) and 6.0, \( f_K/m_\rho = 0.213(42) \) and 0.206(27), where we have added the statistical errors naively in quadrature. The experimental result is 0.208. At present our data at \( \beta = 6.3 \) are too noisy after extrapolation to give a significant result. Finally we note that we have also calculated the decay constant directly from the matrix element of the partially conserved axial current at the points \( m = 0.05 \) and 0.075 at \( \beta = 6.0 \), and the results agree with those using the matrix element of the pseudoscalar density (see Fig. 3).

While the above results indicate good scaling behavior, they must be checked further with improved statistics and a fully covariant fitting procedure. More importantly, the continuum limit still has to be taken: a recent precise calculation using quenched Wilson quarks by the CP-PACS collaboration gives a value for \( f_K/m_\rho \) in the continuum limit that is inconsistent with experiment [12], so the above agreement with experiment may be fortuitous.

In Fig. 4 we show the pion mass squared as a function of \( m \). Lowest order chiral perturbation theory requires \( m_\pi^2 \) to vanish linearly with \( m \). At \( \beta = 6.0 \) our three data points
extrapolate linearly to .008(10), which agrees with the above expectations. At $\beta = 6.3$, the two data points extrapolate to $-0.021(3)$, which is once again likely due to quark masses that are too heavy to agree with lowest order chiral perturbation theory. At $\beta = 5.85$ the two masses extrapolate to $0.045(10)$ for $N_s = 10$ and $0.031(13)$ for $N_s = 14$. This discrepancy is probably not due to higher order terms in the chiral expansion since the physical quark masses are light compared to the masses at the other couplings, and the curvature would have the wrong sign. We see a large downward shift in $m_2^2$ as $N_s$ goes from 10 to 14. However, increasing $N_s$ to 18 at $m = 0.075$ has a negligible effect. This behavior may signal a strong coupling effect where the suppression of explicit chiral symmetry breaking terms with $N_s$ may be weakened. In the case of the vector Schwinger model, it was found that topology changing gauge configurations can induce significant explicit chiral symmetry breaking effects [4]. Further investigation is required.

Our study shows that DWF are an attractive alternative to Kogut-Susskind and Wilson quarks for lattice QCD calculations where chiral symmetry is crucial. For weak matrix elements in particular, DWF yield good agreement with expectations from chiral perturbation theory without the complicated mixing of operators required with Wilson quarks, or the entanglement of flavor and space-time degrees of freedom as with Kogut-Susskind quarks. Perhaps even more importantly, up to exponentially small corrections, DWF maintain the full chiral symmetry of QCD at relatively strong couplings, and thus should have more continuum-like behavior. The data presented here seem to indicate just that, though future studies with improved statistics are needed to confirm this. This improved scaling may compensate for the added cost of the extra dimension.

Our domain wall fermion code relies heavily on the four dimensional MILC code [13], which we are happy to acknowledge again. This research was supported by US DOE grant DE-AC0276CH0016. The numerical computations were carried out on the NERSC T3E.

[12] See the plenary talk by T. Yoshié at Lattice 97.

FIG. 1. The matrix element $\langle \bar{P} | O_{LL} | P \rangle$ vs. $m$. $|P\rangle$ is a non-singlet pseudoscalar state. $m$ is proportional to the quark mass in lattice units. At $\beta = 5.85$ and 6.0 $\langle \bar{P} | O_{LL} | P \rangle$ vanishes linearly with $m$. The slight overshoot at $\beta = 6.3$ is likely due to higher order terms in the chiral expansion (see text).
FIG. 2. Kaon B parameter. The solid line is a pure quadratic fit to the data, and the burst denotes the extrapolation to the continuum limit, $a = 0$. The data are for $N_s = 10$ ($\beta = 6.0, 6.3$) and 14 ($5.85$). The cross (not used in the fit) denotes the partially unquenched result discussed in the text. The energy scale is roughly 2 GeV at $\beta = 6.0$, and perturbative corrections have not been included.
FIG. 3. Pseudoscalar decay constant. Bursts are linear extrapolations to values of $m$ corresponding to the pion and the kaon. $N_s = 10$ and 14 for $\beta = 6.0$ and 5.85, respectively. The crosses denote values calculated from the matrix element of the partially conserved axial current ($\beta = 6.0$ only).
FIG. 4. Pion mass squared. The curve at $\beta = 6.0$ ($N_s = 10$(octagons)) agrees with the expectation from lowest order chiral perturbation theory. The others show small but significant deviations. At $\beta = 5.85$ going from $N_s = 10$ to 14 reduces the discrepancy. However increasing $N_s$ to 18(cross) has no effect. At $\beta = 6.3$, the discrepancy is most likely due to higher order terms in the chiral expansion (see text).
