Abstract

In this conference report a summary is given on the theoretical work that has contributed to provide accurate theoretical predictions for testing the standard model in present and future experiments. Precision calculations for the vector boson masses, for the $Z$ resonance, $W$ pair production, and for the $g - 2$ of the muon are reviewed and the theoretical situation for the Higgs sector is summarized. The status of the standard model is discussed in the light of the recent high and low energy data. New Physics beyond the standard model is briefly addressed as well, with special emphasis on the minimal supersymmetric standard model.

Plenary talk at the
XXIX International Conference on High Energy Physics
Vancouver, Canada, 23 - 29 July 1998
1 Introduction

The $e^+e^-$ colliders LEP and the SLC, in operation since summer 1989, have collected an enormous amount of electroweak precision data on $Z$ and $W$ bosons. The $W$ boson properties have in parallel been determined at the $p\bar{p}$ collider Tevatron with a constant increase in accuracy; after the discovery of the top quark there, its mass has been measured with a precision of better than 3%, to $173.8\pm5.0$ GeV. The ongoing experiments at LEP 2 and the near-future Tevatron upgrade will also, in the coming years, support us with further increases in precision, in particular on the mass of the $W$ and the top, and the SLC might continue to improve the impressive accuracy already obtained in the electroweak mixing angle. This stimulating experimental program together with the theoretical activities to provide accurate predictions from the standard model have formed the era of electroweak precision tests and will keep it alive also in the next years.

The standard theory of the electroweak interaction is a gauge-invariant quantum field theory with the symmetry group $SU(2)\times U(1)$ spontaneously broken by the Higgs mechanism. The possibility to perform perturbative calculations for observable quantities in terms of a few input parameters is substantially based on the renormalizability of this class of theories. A certain set of input parameters has to be taken from experiment. In the electroweak standard model essentially three free parameters are required to describe the gauge bosons $\gamma, W^\pm, Z$, and their interactions with the fermions. For a comparison between theory and experiment, hence, three independent experimental input data are required. The most natural choice consists of the electromagnetic fine structure constant $\alpha$, the muon decay constant ($F$), and the mass of the $Z$ boson, which has meanwhile been measured with the same accuracy as the Fermi constant $F$. Other measurable quantities are predicted in terms of the input data. Each additional precision experiment, which allows the detection of small deviations from the lowest-order predictions, can be considered a test of the electroweak theory at the quantum level. In the Feynman graph expansion of the scattering amplitude for a given process the higher-order terms show up as diagrams containing closed loops. The renormalizability of the standard model ensures that it retains its predictive power also in higher orders. The higher-order terms are the quantum effects of the electroweak theory. They are complicated in their concrete form, but they are finally the consequence of the basic Lagrangian with a simple structure. The quantum corrections (or “radiative corrections”) contain the self-coupling of the vector bosons as well as their interactions with the Higgs field and the top quark, and provide the theoretical basis for electroweak precision tests. Assuming the validity of the standard model, the presence of the top quark and the Higgs boson in the loop contributions to electroweak observables allows an indirect probe of their mass ranges from comparison with precision data.

The generation of high-precision experiments hence imposes stringent tests on the standard model. A primordial step strengthening our confidence in the standard model has been the discovery of the top quark at the Tevatron, at a mass that agrees with the mass range obtained indirectly, through the radiative corrections. Moreover, with the top mass as an additional precise experimental data point one can now fully exploit the virtual sensitivity to the Higgs mass.

The experimental sensitivity in the electroweak observables, at the level of the quantum effects, requires the highest standards on the theoretical side as well. A sizeable amount of work has contributed, over the recent years, to a steadily rising improvement of the standard model predictions, pinning down the theoretical uncertainties to the level required for the current interpretation of the precision data. The availability of both highly accurate measurements and theoretical predictions, at the
The mass of the Higgs boson, as long as it is experimen-
tally unknown, is treated as a free input parameter. In
the electroweak theory the classical Thomson scattering
to define the physical input parameters. In QED and in
the hadronic contribution
Re \hat{\Pi} (M_Z^2) \equiv Re \hat{\Pi}^{\mu} (M_Z^2) = \Pi^\mu (0) \tag{1}

of the photon vacuum polarization is a basic entry in the
predictions for electroweak precision observables. The
purely fermionic contributions correspond to standard
QED and do not depend on the details of the electroweak
theory. They are conveniently split into a leptonic and a
hadronic contribution
\text{Re}\hat{\Pi}^\gamma (M_Z^2)_{\text{term}} = \text{Re}\hat{\Pi}^{\gamma}_{\text{lep}} (M_Z^2) + \text{Re}\hat{\Pi}^{\gamma}_{\text{had}} (M_Z^2) \tag{2}

where the top quark is not included in the hadronic part
(5 light flavours); it yields a small non-logarithmic con-
tribution
\hat{\Pi}^{\gamma}_{\text{lep}} (M_Z^2) \simeq \frac{\alpha}{\pi} \frac{Q_t^2}{5 m_t^2} \simeq 0.57 \cdot 10^{-4} \tag{3}

The quantity
\Delta \alpha = \Delta \alpha_{\text{lep}} + \Delta \alpha_{\text{had}}
= - \text{Re}\hat{\Pi}^{\gamma}_{\text{lep}} (M_Z^2) - \text{Re}\hat{\Pi}^{\gamma}_{\text{had}} (M_Z^2) \tag{4}
corresponds to a QED-induced shift in the electromagnetic fine structure constant

$$\alpha \rightarrow \alpha(1 + \Delta\alpha),$$

(5)

which can be resummed according to the renormalization group accommodating all the leading logarithms of the type \(\alpha^n \log^n(M_Z/m_f)\). The result can be interpreted as an effective fine structure constant at the Z mass scale:

$$\alpha(M_Z^2) = \frac{\alpha}{1 - \Delta\alpha}.$$  

(6)

It corresponds to a resummation of the iterated 1-loop vacuum polarization from the light fermions to all orders. \(\Delta\alpha\) is an input of crucial importance because of its universality and of its remarkable size of \(~6\%\). The leptonic content can be directly evaluated in terms of the known lepton masses, yielding at one loop order:

$$\Delta\alpha_{\text{lept}} = \sum_{\ell=e,\mu,\tau} \frac{\alpha}{3\pi} \left( \log \frac{M_Z^2}{m_{\ell}^2} \right)^{5/3} + O\left( \frac{m_{\tau}^2}{M_Z^2} \right).$$

(7)

The 2-loop correction has been known already for a long time\(^{27}\), and also the 3-loop contribution is now available\(^{28}\), yielding altogether

$$\Delta\alpha_{\text{lept}} = 314.97687 \times 10^{-4} = [314.19007 \text{-loop} + 0.776172 \text{-loop} + 0.01063 \text{-loop}] \times 10^{-4},$$  

(8)

For the light hadronic part, perturbative QCD is not applicable and quark masses are not available as reasonable input parameters. Instead, the 5-flavour contribution to \(\Pi_{\text{had}}\) can be derived from experimental data with the help of a dispersion relation

$$\Delta\alpha_{\text{had}} = -\frac{\alpha}{3\pi} M_Z^2 \text{Re} \int_{4m_{\ell}^2}^{\infty} ds' \frac{R^\ell(s')}{s'(s' - M_Z^2 - i\varepsilon)}$$

(9)

with

$$R^\ell(s) = \frac{\sigma(e^+e^- \rightarrow \gamma^* \rightarrow \text{hadrons})}{\sigma(e^+e^- \rightarrow \gamma^* \rightarrow \mu^+\mu^-)}$$

as an experimental input quantity in the problematic low energy range.

Integrating by means of the trapezoidal rule (averaging data in bins) over \(e^+e^-\) data for the energy range below 40 GeV and applying perturbative QCD for the high-energy region above, the expression (9) yields the value\(^{29,30}\)

$$\Delta\alpha_{\text{had}} = -0.0280 \pm 0.0007,$$

(10)

which agrees with another independent analysis\(^{31}\) with a different error treatment. Because of the lack of precision in the experimental data a large uncertainty is associated with the value of \(\Delta\alpha_{\text{had}}\), which propagates into the theoretical error of the predictions of electroweak precision observables. Including additional data from \(\tau\)-decays\(^{32}\) yields about the same result with a slightly improved uncertainty. Recently other attempts have been made to increase the precision of \(\Delta\alpha\)\(^{33,35-37}\) by “theory-driven” analyses of the dispersion integral (9). The common basis is the application of perturbative QCD down to the energy scale given by the \(\tau\) mass for the calculation of the quantity \(R^\ell(s)\) outside the resonances. Those calculations were made possible by the recent availability of the quark-mass-dependent \(O(\alpha_s^2)\) QCD corrections\(^{38}\) for the cross section down to close to the thresholds for \(b\) and \(c\) production. [A first step in this direction was done in\(^{39}\) in the massless approximation.] In order to pin down the error, two different strategies are in use: the application of the method developed in\(^{36}\) for minimizing the impact of data from less reliable regions, done in\(^{33}\), and the rescaling of data in the open charm region of 3.7–5 GeV from PLUTO/DASP/MARKII, for the purpose of normalization to agree with perturbative QCD, done in\(^{35}\).

The results obtained for \(\Delta\alpha_{\text{had}}\) are very similar:

$$0.02763 \pm 0.0016 \text{ ref}^{35}$$

$$0.02777 \pm 0.0017 \text{ ref}^{35}$$

In\(^{37}\) the \(\overline{MS}\) quantity \(\hat{\alpha}(M_Z)\) has been derived with the help of an unsubtracted dispersion relation in the \(\overline{MS}\) scheme, yielding a comparable error. The history of the determination of the hadronic vacuum polarization is visualized in Figure 1.

![Figure 1: Various determinations of \(\Delta\alpha_{\text{had}}\) (from ref\(^{34}\)).](image-url)

The basic assumption in the theory-driven approach, the validity of perturbative QCD and quark-hadron duality, is supported by the following empirical observations:

- The strong coupling constant \(\alpha_s(m_\tau)\) determined from hadronic \(\tau\) decays shows good agreement with
\( \alpha_s(M_Z) \) determined from Z-peak observables when the renormalization group evolution of \( \alpha_s \) in perturbative QCD is imposed to run \( \alpha_s \) from \( m_t \) to the Z-mass scale.

- Non-perturbative contributions in \( R'(s) \), parametrized in terms of condensates of quarks, gluons and of vacuum expectation values of higher-dimensional operators in the operator product expansion \( 40 \) can be probed by comparing spectral moments of \( R'_{\text{exp}}(s) \) with the corresponding expressions involving the theoretical \( R' \). It has been shown from fitting a set of moments that the non-perturbative contributions are negligibly small \( 33,34 \).

- Recent preliminary measurements of \( R' \) at BES at 2.6 and 3.3 GeV show values slightly lower than the previous data \( 31,32 \), better in alignment with the expectations from perturbative QCD.

Although the error in the QCD-based evaluation of \( \Delta\alpha_{\text{had}} \) is considerably reduced, it should be kept in mind that the conservative estimate in Eq. (10) is independent of theoretical assumptions on QCD at lower energies and thus less sensitive to potential systematic effects not under consideration now \( 42 \).

(ii) Mixing angle renormalization and the \( \rho \)-parameter:
The \( \rho \)-parameter, originally defined as the ratio of the neutral to the charged current strength in neutrino scattering \( 43 \), is unity in the standard model at the tree level, but gets a deviation \( \Delta \rho \) from 1 by radiative corrections. The dominating universal part has its origin in the renormalization of the relation between the gauge boson masses and the electroweak mixing angle. This relation is modified in higher orders according to

\[
\sin^2 \theta_W = 1 - \frac{M_W^2}{M_Z^2} + \frac{M_W^2}{M_Z^2} \Delta \rho + \cdots
\]

The main contribution to the universal \( \rho \)-parameter

\[
\rho = \frac{1}{1 - \Delta \rho}
\]

is from the \( (t, b) \) doublet \( 44 \), at the present level calculated as follows:

\[
\Delta \rho = 3 x_t \cdot [1 + x_t \rho^{(2)} + \delta \rho_{\text{QCD}}]
\]

with

\[
x_t = \frac{G_F m_t^2}{8 \pi^2 \sqrt{2}}.
\]

The electroweak 2-loop part \( 45,46 \) is described by the function \( \rho^{(2)}(M_H/m_t) \), and \( \delta \rho_{\text{QCD}} \) is the QCD correction to the leading \( G_F m_t^2 \) term \( 47,48 \).

\[
\delta \rho_{\text{QCD}} = -\frac{\alpha_s(\mu)}{\pi} c_1 + \left(\frac{\alpha_s(\mu)}{\pi}\right)^2 c_2(\mu)
\]

with

\[
c_1 = \frac{2}{3} \left( \frac{\pi^2}{3} + 1 \right) = 2.8599
\]

and the 3-loop coefficient \( 48 \) \( c_2(\mu) \), which amounts to

\[
c_2 = -14.59 \text{ for } \mu = m_t \text{ and } 6 \text{ flavours}
\]

with the on-shell top mass \( m_t \). This reduces the scale dependence of \( \rho \) significantly and hence is an important entry to decrease the theoretical uncertainty of the standard model predictions for precision observables.

There is also a Higgs contribution to \( \Delta \rho \), which, however, is not UV-finite by itself when derived from only the diagrams involving the physical Higgs boson. The \( M_H \)-dependence for large Higgs masses \( M_H \) is only logarithmic in 1-loop order \( 49 \); the 2-loop contribution \( 50 \) shows a dependence \( \sim M_H^2 \) for large values of the Higgs mass. In the limit \( \sin^2 \theta_W \to 0 \), \( M_Z \to M_W \), where the \( U(1)_Y \) is switched off, one finds \( \Delta \rho_{\text{H}} = 0 \). This is the consequence of the global \( SU(2)_R \) symmetry of the Higgs Lagrangian (‘custodial symmetry’), which is broken by the \( U(1)_Y \) group. Thus, \( \Delta \rho_{\text{H}} \) is a measure of the \( SU(2)_R \) breaking by the weak hypercharge.

2.2 Muon decay and the vector boson masses

The interdependence between the gauge boson masses is established through the accurately measured muon lifetime or, equivalently, the Fermi coupling constant \( G_{\mu} \). Originally, the \( \mu \)-lifetime \( \tau_{\mu} \) has been calculated within the framework of the effective 4-point Fermi interaction. Beyond the well-known 1-loop QED corrections \( 51 \), the 2-loop QED corrections in the Fermi model have been calculated quite recently \( 52 \), yielding the expression (the error in the 2-loop term is from the hadronic uncertainty)

\[
\frac{1}{\tau_{\mu}} = \frac{G_{\mu}^2 m_{\mu}^5}{192 \pi^3} \left( 1 - \frac{m_e^2}{m_{\mu}^2} \right) \cdot \left[ 1 + 1.810 \frac{\alpha}{\pi} + (6.701 \pm 0.002) \left( \frac{\alpha}{\pi} \right)^2 \right].
\]

This formula is the defining equation for \( G_{\mu} \) in terms of the experimental \( \mu \)-lifetime. Owing to the presence of order-dependent QED corrections, the numerical value of the Fermi constant changes after the second-order term is included. Compared with the value given in the 1998 report of the Particle Data Group \( 53 \), the latest value is now smaller by \( 2 \cdot 10^{-10} \text{ GeV}^{-2} \), namely \( 52 \)

\[
G_{\mu} = (1.16637 \pm 0.00001) \cdot 10^{-5} \text{ GeV}^{-2} ,
\]

where also the error has been reduced by a factor of about \( 1/2 \).

In the standard model, \( G_{\mu} \) can be calculated including quantum corrections in terms of the basic standard
model parameters, thereby separating off all diagrams that correspond to the QED corrections in the Fermi model. This yields the correlation between the masses $M_W, M_Z$ of the vector bosons, expressed in terms of $\alpha$ and $G_\mu$; in 1-loop order it is given by:

$$G_\mu = \frac{\pi \alpha}{2 s_W^2 M_W} [1 + \Delta r(\alpha, M_W, M_Z, M_H, m_t)].$$  \hspace{1cm} (18)

with $s_W^2 = 1 - M_W^2/M_Z^2$.

The decomposition

$$\Delta r = \Delta \alpha - \frac{e^2}{s_W^2} \Delta \rho^{(1)} + (\Delta r)_{\text{rem}}$$  \hspace{1cm} (19)

separates the leading fermionic contributions $\Delta \alpha$ and $\Delta \rho(1\text{-loop})$. All other terms are collected in the remainder part $(\Delta r)_{\text{rem}}$, the typical size of which is of order $\sim 0.01$.

The presence of large terms in $\Delta r$ requires the consideration of effects higher than 1-loop (see also the contribution by Kühn $^{54}$ to these proceedings). The modification of Eq. (18) according to

$$1 + \Delta r \rightarrow \frac{1}{(1 - \Delta \alpha)(1 + \frac{e^2}{s_W^2} \Delta \rho) - (\Delta r)_{\text{rem}}}$$

$$\equiv \frac{1}{1 - \Delta r}$$  \hspace{1cm} (20)

accommodates the following higher-order terms $(\Delta r$ in the denominator is an effective correction including higher orders):

(i) the leading log resummation $^{55}$ of $\Delta \alpha$: $1 + \Delta \alpha \rightarrow (1 - \Delta \alpha)^{-1}$;

(ii) the resummation of the leading $m_t^2$ contribution $^{56}$ in terms of $\Delta \rho$ in Eq. (13). Beyond the QCD higher-order contributions through the $\rho$-parameter, the complete $O(\alpha \alpha_s)$ corrections to the self energies are available $^{57,58}$. All these higher-order terms contribute with the same positive sign to $\Delta r$. Non-leading QCD corrections to $\Delta r$ of the type

$$\Delta r_{(bt)} = 3 x_t \left( \frac{\alpha_s}{\pi} \right)^2 \left( a_1 \frac{M_Z^2}{m_t^2} + a_2 \frac{M_W^2}{m_t^2} \right)$$

are also available $^{59}$.

(iii) With the quantity $(\Delta r)_{\text{rem}}$ in the denominator, non-leading higher-order terms containing mass singularities of the type $\alpha^2 \log(M_Z/m_f)$ from light fermions are incorporated $^{60}$.

(iv) The subleading $G_\mu^2 m_t^2 M_Z^2$ contribution of the electroweak 2-loop order $^{61}$ in an expansion in terms of the top mass. This subleading term turned out to be sizeable, about as large as the formally leading term of $O(m_t^4)$ via the $\rho$-parameter. In view of the present and future experimental accuracy it constitutes a non-negligible shift in the $W$ mass.

Meanwhile exact results have been derived for the Higgs-dependence of the fermionic 2-loop corrections in $\Delta r$ $^{62}$, and comparisons were performed with those obtained via the top mass expansion $^{63}$. Differences in the values of $M_W$ of several MeV (up to 8 MeV) are observed when $M_H$ is varied over the range from 65 GeV to 1 TeV.

Figure 2 shows the Higgs-mass dependence of the two-loop corrections to $\Delta r$ associated with the $t/b$ doublet, with $\Delta \alpha$, and with the light fermion terms not in $\Delta \alpha$, together with the leading $m_t^4$-term, which constitutes a very poor approximation.

Pure fermion-loop contributions ($n$ fermion loops at $n$-loop order) have also been investigated $^{63,64}$. In the on-shell scheme, explicit results have been worked out up to 4-loop order, which allows an investigation of the validity of the resummation (20) for the non-leading 2-loop and higher-order terms. It was found that numerically the resummation (20) works remarkably well, within 2 MeV in $M_W$.

![Figure 2: Higgs mass dependence of fermionic contributions to $\Delta r$ at the two-loop level (from $^{63}$). The different curves show the various contributions: light fermions via $\Delta \alpha$ ($\Delta r_{\Delta \alpha}$), residual light-fermion contribution not in $\Delta \alpha$ ($\Delta r_{(\Delta r_{\Delta \alpha})}$), the contribution from the $(tb)$ doublet ($\Delta r_{(tb)}$), and the approximation of the $(tb)$ two-loop contribution by the term proportional to $m_t^4$. Displayed in each case is the difference $\Delta r(M_H) - \Delta r(100 \text{GeV})$.](image)

### 2.3 Z boson observables

Measurements of the $Z$ line shape in $e^+e^- \rightarrow f\bar{f}$ yield the parameters $M_Z, \Gamma_Z$, and the partial widths $\Gamma_f$ or the peak cross section

$$\sigma_f = \frac{12 \pi}{M_Z^2} \frac{\Gamma_f \Gamma_f}{\Gamma_Z}.$$  \hspace{1cm} (21)
Angular distributions and polarization measurements of the final fermions yield forward–backward and polarization asymmetries. Whereas $M_Z$ is used as a precise input parameter, together with $\alpha$ and $G_\mu$, the width, partial widths and asymmetries allow comparisons with the predictions of the standard model. The predictions for the partial widths as well as for the asymmetries can conveniently be calculated in terms of effective neutral current coupling constants for the various fermions.

**Effective Z boson couplings:** The effective couplings follow from the set of 1-loop diagrams without virtual photons, the non-QED or weak corrections. These weak corrections can conveniently be written in terms of fermion-dependent overall normalizations $\rho_f$ and effective mixing angles $s_f^2$ in the NC vertices (see e.g.\(^{55}\)):

$$J_{\nu}^{NC} = \left(\sqrt{2} G_\mu M_Z \right)^{1/2} \left( g_{f \gamma}^f g_\gamma^f \right)$$

$$= \left(\sqrt{2} G_\mu M_Z^2 \rho_f \right)^{1/2} \left( I_{f}^3 - 2Q_f s_f^2 \right) \gamma_\nu - I_{f}^1 \gamma_\nu \gamma_5 \right).$$

$\rho_f$ and $s_f^2$ contain universal parts, e.g. from the $\rho$-parameter via

$$\rho_f = \frac{1}{1-\Delta \rho} + \cdots, \quad s_f^2 = s_W^2 + c_W^2 \Delta \rho + \cdots$$

with $\Delta \rho$ from Eq. (13) and non-universal parts that explicitly depend on the type of the external fermions.

The subleading 2-loop corrections $\sim G_\mu^2 m_f^2 M_Z^2$ for the leptonic mixing angle $\theta_{\ell \ell}$ have also been obtained in the meantime, as well as for $\rho_\tau$.\(^{66}\)

Meanwhile exact results have been derived for the Higgs-dependence of the fermionic 2-loop corrections in $s_f^2$\(^{63,64}\), and comparisons were performed with those obtained via the top mass expansion $^{63}$. Differences in the values of $s_f^2$ can amount to $0.8 \cdot 10^{-4}$ when $M_H$ is varied over the range from 100 GeV to 1 TeV.

Figure 3 shows the Higgs-mass dependence of the 2-loop corrections to $s_f^2$ associated with the $t/b$ doublet, with $\Delta \alpha$, and with the light fermion terms not in $\Delta \alpha$. As can be seen, the $M_H$-dependence of the light fermions yields contributions to $s_f^2$ up to $2 \cdot 10^{-5}$. For $\rho_\tau$ or equivalently the leptonic $Z$ widths, the subleading 2-loop effects are small, and differences with the results in the top mass dependence are irrelevant.

For the $b$ quark coupling to the $Z$ boson, not only the universal contribution through the $\rho$-parameter but also the non-universal parts have a strong dependence on $m_t$, resulting from virtual top quarks in the vertex corrections. The difference between the $d$ and $b$ couplings can be parametrized in the following way

$$\rho_b = \rho_d(1 + \tau)^2, \quad s_b^2 = s_d^2(1 + \tau)^{-1},$$

with the quantity

$$\tau = \Delta \tau^{(1)} + \Delta \tau^{(2)} + \Delta \tau^{(\alpha_\ell)}$$

calculated perturbatively, including the complete 1-loop order term $^{67}$ with $x_t$ from Eq. (14):

$$\Delta \tau^{(1)} = -2 x_t - \frac{G_\mu M_Z^2}{6 \pi^2 \sqrt{2} (\tau_W^2 + 1) \log \frac{m_t}{M_W}} + \cdots,$$

and the leading electroweak 2-loop contribution of $O(G_\mu^2 m_t^4)$.\(^{46,68}\)

$$\Delta \tau^{(2)} = -2 x_t^2 \tau^{(2)},$$

where $\tau^{(2)}$ is a function of $M_H/m_t$ with $\tau^{(2)} = 9 - \pi^2/3$ for small $M_H$.

**Asymmetries and mixing angles:** The effective mixing angles are of particular interest, since they determine the on-resonance asymmetries via the combinations

$$A_f = \frac{2 g_{f \gamma}^f g_A^f}{(g_{f \gamma}^f)^2 + (g_A^f)^2},$$

namely

$$A_{FB} = \frac{3}{4} A_e A_f, \quad A_{\tau}^{pol} = A_\tau, \quad A_{LR} = A_e.$$

Measurements of the asymmetries hence are measurements of the ratios

$$g_{f \gamma}^f / g_A^f = 1 - 2 Q_f s_f^2$$

or the effective mixing angles, respectively.
QCD corrections were first derived for the leading term pure QCD corrections, also the 2-loop contributions of sensitivity to the top quark mass. Therefore, beyond the are known to \(O\) in fermion masses: 

\[
\Gamma_f = \Gamma_0 \left[ (g_V^f)^2 + (g_A^f)^2 \left( 1 - \frac{6m_f^2}{M_Z^2} \right) \right] + \Delta \Gamma_{QCD}^f
\]

with 

\[
\Gamma_0 = N_C \frac{\sqrt{2} G_F M_Z^3}{12 \pi}, \quad N_C^f = 1 \text{ (leptons)}, = 3 \text{ (quarks)}.
\]

The QCD correction for the light quarks with \(m_q \simeq 0\) is given by 

\[
\Delta \Gamma_{QCD}^f = \Gamma_0 \left[ (g_V^f)^2 + (g_A^f)^2 \right] K_{QCD} \tag{30}
\]

with 

\[
K_{QCD} = \frac{\alpha_s}{\pi} + 1.41 \left( \frac{\alpha_s}{\pi} \right)^2 - 12.8 \left( \frac{\alpha_s}{\pi} \right)^3 - \frac{Q_f^2}{4} \frac{\alpha_s}{\pi}.
\]

For \(b\) quarks the QCD corrections are different, because of finite \(b\) mass terms and to top-quark-dependent 2-loop diagrams for the axial part: 

\[
\Delta \Gamma_{QCD}^{b} = \Delta \Gamma_{QCD}^{d} + \Gamma_0 \left[ (g_V^{b})^2 R_V + (g_A^{b})^2 R_A \right]. \tag{31}
\]

The coefficients in the perturbative expansions 

\[
R_V = c_1 \frac{\alpha_s}{\pi} + c_2 \left( \frac{\alpha_s}{\pi} \right)^2 + c_3 \left( \frac{\alpha_s}{\pi} \right)^3 + \cdots,
\]

\[
R_A = c_4 \frac{\alpha_s}{\pi} + c_5 \left( \frac{\alpha_s}{\pi} \right)^2 + \cdots
\]

depending on \(m_b\) and \(m_t\), are calculated up to third order in \(\alpha_s\), except for the \(m_t\)-dependent singlet terms, which are known to \(O(\alpha_s^3)\) \(^{70,71}\). For a review of the QCD corrections to the \(Z\) width, see \(^{72}\).

The partial decay rate into \(b\)-quarks, in particular the ratio \(R_b = \Gamma_b/\Gamma_{had}\), is an observable of special sensitivity to the top quark mass. Therefore, beyond the pure QCD corrections, also the 2-loop contributions of the mixed QCD–electroweak type, are important. The QCD corrections were first derived for the leading term of \(O(\alpha_s G_F m_t^2)\) \(^{73}\) and were subsequently collected by the \(O(\alpha_s)\) correction to the \(m_t/M_W\) term \(^{74}\) and the residual terms of \(O(\alpha_s^2)\) \(^{75}\).

In the same spirit, also the complete 2-loop \(O(\alpha_s)\) to the partial widths into the light quarks have been obtained, beyond those that are already contained in the factorized expression \(30\) with the electroweak 1-loop couplings \(^{76}\). These “non-factorizable” corrections yield an extra negative contribution of \(-0.55(3)\) MeV to the total hadronic \(Z\) width (converted into a shift of the strong coupling constant, they correspond to \(\delta \alpha_s = 0.001\)). In summary, the 2-loop corrections of \(O(\alpha_s)\) to the electroweak precision observables are by now completely under control. More details can be found in \(^{54}\).

Radiation of secondary fermions through photons from the primary final state fermions can yield another sizeable contribution to the partial \(Z\) widths; however, this is compensated by the corresponding virtual contribution through the dressed photon propagator in the final-state vertex correction for sufficiently inclusive final states, i.e., for loose cuts to the invariant mass of the secondary fermions \(^{77}\).

QED corrections: The observed cross section is the result of convoluting the cross section for \(e^+ e^- \rightarrow f \bar{f}\) calculated on the basis of the effective couplings with the initial-state QED corrections consisting of virtual photon and real photon bremsstrahlung contributions:

\[
\sigma_{obs}(s) = \int_{0}^{k_{max}} dk H(k) \sigma(s(1 - k)); \tag{32}
\]

\(k_{max}\) denotes a cut to the radiated energy. Kinematically it is limited by \(1 - 4m_\ell^2/s\) or \(1 - 4m_\nu^2/s\) for hadrons, respectively. For the required accuracy, multiphoton radiation has to be included. The radiator function \(H(k)\) with soft-photon resummation and the exact \(O(\alpha^2)\) result for initial-state QED corrections is given in ref \(^{78}\). It has been improved recently by the \(O(\alpha^3)\) term \(^{79}\).

Bhabha scattering in the forward direction is the crucial theoretical tool for the determination of the luminosity and therefore requires a careful treatment, including higher-order QED corrections \(^{80}\). Improvements in the calculation of the \(O(\alpha^2)\) next-to-leading logarithmic contributions in the Monte Carlo generator BHLUMI are an important step in pinning down the theoretical error from 0.11% to 0.06% \(^{81}\).

2.4 Accuracy of the standard model predictions

For a discussion of the theoretical reliability of the standard model predictions, one has to consider the various sources contributing to their uncertainties:

**Parametric uncertainties** result from the limited precision in the experimental values of the input parameters, essentially \(\alpha_s = 0.119 \pm 0.002\) \(^{53}\), \(m_t = 173.8 \pm 5.0\) GeV \(^5\), \(m_h = 47.7 \pm 0.2\) GeV, and the hadronic vacuum polarization as discussed in section 2.1. The conservative estimate of the error in Eq. (10) leads to \(\delta M_W = 13\) MeV in the \(W\)-mass prediction, and \(\delta \sin^2 \theta = 0.00023\) common to all of the mixing angles.

The uncertainties from the QCD contributions can essentially be traced back to those in the top quark loops
in the vector boson self-energies. The knowledge of the $O(\alpha_s^2)$ corrections to the $\rho$-parameter and $\Delta r$ yields a significant reduction; they are small, although not negligible (e.g. $\sim 3 \cdot 10^{-5}$ in $s^2_t$).

The size of unknown higher-order contributions can be estimated by different treatments of non-leading terms of higher order in the implementation of radiative corrections in electroweak observables (‘options’) and by investigations of the scheme dependence. Explicit comparisons between the results of 5 different computer codes based on on-shell and $\overline{MS}$ calculations for the $Z$-resonance observables are documented in the “Electroweak Working Group Report”\textsuperscript{65} in ref\textsuperscript{26}. The inclusion of the non-leading 2-loop corrections $\sim G_F^2 m_t^2 M_Z^2$ reduce the uncertainty in $M_W$ below 10 MeV and in $s^2_t$ below $10^{-4}$, typically to $\pm 4 \cdot 10^{-5}$.

3 Standard model and precision data

We now confront the standard model predictions for the discussed set of precision observables with the most recent sample of experimental data\textsuperscript{1,2}. In table 1 the standard model predictions for $Z$-pole observables and the $W$ mass are put together for the best fit input data set, given in (34). The experimental results on the $Z$ observables are from LEP and the SLC, the $W$ mass is from combined LEP and $pp$ data. The leptonic mixing angle determined via $A_{LR}$ by the SLD experiment\textsuperscript{82} and the $s^2_t$ average from LEP:

$$s^2_t(\text{SLD}) = 0.23109 \pm 0.00029$$

$$s^2_t(\text{LEP}) = 0.23189 \pm 0.00024$$

have come closer to each other in their central value; owing to their smaller errors, however, they still differ by 2.8 standard deviations.

Table 1 contains the combined LEP/SLD value. $\rho_t$ and $s^2_t$ are the leptonic neutral current couplings in Eq. (22), derived from partial widths and asymmetries under the assumption of lepton universality.

Note that the experimental value for $\rho_t$ points at the presence of genuine electroweak corrections by 3.5 standard deviations. In $s^2_t$ the presence of purely bosonic radiative corrections is clearly established when the experimental result is compared with a theoretical value containing only the fermion loop corrections, an observation that has been persisting already for several years\textsuperscript{83}. The deviation from the standard model prediction in the quantity $R_h$ has been reduced below one standard deviation by now. Other small deviations are observed in the asymmetries: the purely leptonic $A_{FB}$ is slightly higher than the standard model predictions, and $A_{FB}$ for $b$ quarks is lower. Whereas the leptonic $A_{FB}$ favours a very light Higgs boson, the $b$ quark asymmetry needs a heavy Higgs.

The effective mixing angle is an observable most sensitive to the mass $M_H$ of the Higgs boson. Since a light Higgs boson corresponds to a low value of $s^2_t$, the strongest upper bound on $M_H$ is from $A_{LR}$ at the SLC\textsuperscript{82}. The inclusion of the two-loop electroweak corrections $\sim m_t^2$ from\textsuperscript{84} yields a sizeable positive contribution to $s^2_t$, see Figure 4. The inclusion of this term hence strengthens the upper bound on $M_H$.

The $W$ mass prediction in table 1 is obtained from Eq. (18) (including the higher-order terms) from $M_Z$, $G_F$, $\alpha$ and $M_H$, $m_t$. The present experimental value for the $W$ mass from the combined LEP 2, UA2, CDF and D0 results is in best agreement with the standard model prediction.

The quantity $s^2_{FW}$ resp. the ratio $M_W/M_Z$ can indirectly be measured in deep-inelastic neutrino-nucleon scattering. The average from the experiments CCFR, CDHS and CHARM\textsuperscript{85} with the recent NUTEV result\textsuperscript{86}.

$$s^2_{FW} = 1 - M_W^2/M_Z^2 = 0.2255 \pm 0.0021$$

for $m_t = 175$ GeV and $M_H = 150$ GeV corresponds to $M_W = 80.25 \pm 0.11$ GeV and is hence fully consistent with the direct vector boson mass measurements and with the standard theory.

8
Standard model global fits: The FORTRAN codes ZFITTER and TOPAZO have been updated by incorporating all the recent precision calculation results that were discussed in the previous section. Comparisons have shown good agreement between the predictions from the two independent programs. Global fits of the standard model parameters to the electroweak precision data done by the Electroweak Working Group are based on these recent versions. Including $m_t$ and $M_W$ from the direct measurements in the experimental data set, together with $s_W^2$ from neutrino scattering, the standard model parameters for the best fit result are:

\[ m_t = 171.1 \pm 4.9 \text{GeV} \]
\[ M_H = 76.2^{+8.5}_{-4.7} \text{GeV} \]
\[ \alpha_s = 0.119 \pm 0.003. \]  

The upper limit to the Higgs mass at the 95% C.L. is $M_H < 262$ GeV, where the theoretical uncertainty is included. Thereby the hadronic vacuum polarization in Eq. (10) has been used (solid line in Figure 6). With the theory-driven result on $\Delta \alpha_{\text{had}}$ of ref. 33 one obtains $M_H = 92^{+64}_{-41}$ (dashed line). The 1σ upper bound on $M_H$ is influenced only marginally. The reason is that simultaneously with the error reduction the central value of $M_H$ is shifted upwards (see Figure 6). Another recent analysis (for earlier studies see ref. 34) based on the data set of summer 1998 yields a Higgs mass $M_H = 107^{+67}_{-45}$ GeV. About one half of the difference with (34) can be ascribed to the use of $\alpha(Z)$ of ref. 37, which is very close to the value in ref. 33,35; the residual shift might be interpreted as due to different renormalization schemes and different treatments of $\alpha_s$.

With an overall $\chi^2$/d.o.f. $= 15/15$ the quality of the fit is remarkably high. As can be seen from Figure 5, the deviation of the individual quantities from the standard model best-fit values are below 2 standard deviations.

Compared with the results from 1997, the central value for the Higgs mass has moved to lower values and the error has been decreased. The Higgs mass bounds follow from the $\chi^2$ distribution shown in Figure 6. The shift in the central value can be understood from Figure 7, which illustrates the effect of the inclusion of the electroweak two-loop contribution by Degrassi et al. 61, which was not implemented in the codes for the analysis in 1997. Since it increases the prediction for $s_W^2$ (Figure 4) for a given Higgs mass, the allowed values of $M_H$ are shifted accordingly downwards.

The second observation is the decrease of the error, which besides the experimental improvements results from the reduction of the theoretical uncertainties of pure electroweak origin. The shaded band around the solid line in Figure 6 is the influence of the various ‘options’
(see section 2.4) in the codes ZFITTER and TOPAZ0 after the implementation of the 2-loop electroweak terms $\sim m_t^2$. It is thus the direct continuation of the error estimate done in the previous study\textsuperscript{65}. Compared with the width of the uncertainty band in 1997\textsuperscript{1} the shrinking is evident.

On the other hand, the remaining theoretical uncertainty associated with the Higgs mass bounds should be taken very seriously. The effect of the inclusion of the next-to-leading term in the $m_t$-expansion of the electroweak 2-loop corrections in the precision observables has shown to be sizeable, at the upper margin of the estimate given in\textsuperscript{65}. It is thus not guaranteed that the subsequent subleading terms in the $m_t$-expansion are indeed smaller in size. Kühn\textsuperscript{54} has given an example for an explicit calculation where the subleading terms of the $m_t$-expansion are of comparable size and tend to cancel each other. Also the variation of the $M_H$-dependence at different stages of the calculation, as discussed in sections 2.2 and 2.3, indicate the necessity of more complete results at two-loop order. Having in mind also the variation of the Higgs mass bounds under the fluctuations of the experimental data\textsuperscript{2}, the limits for $M_H$ derived from the analysis of electroweak data in the frame of the standard model still carry a noticeable uncertainty. Nevertheless, as a central message, it can be concluded that the indirect determination of the Higgs mass range has shown that the Higgs is light, with its mass well below the non-perturbative regime.

4 Production and decay of $W$ bosons

The success of the standard model in the correct description of the electroweak precision observables is simultaneously an indirect confirmation of the Yang–Mills structure of the gauge boson self-interaction. For conclusive confirmations the direct experimental investigation is required. At LEP 2 (and higher energies), pair production of on-shell $W$ bosons can be studied experimentally, allowing tests of the trilinear vector boson self-couplings and precise $M_W$ measurements. For LEP 2, an error of about 40 MeV in $M_W$ can be reached.\textsuperscript{93} For this purpose standard model calculations for the process $e^+e^-\rightarrow W^+W^-\rightarrow 4f$ and the corresponding 4-fermion background processes are mandatory at the accuracy level of at least 1%. This requires the understanding of the radiative corrections to the $W$ boson production and decay processes, as well as a careful treatment of the finite-widths effects.

For practical purposes, improved Born approximations are in use for both resonating and non-resonating processes, dressed by initial-state QED corrections. A status report can be found in ref\textsuperscript{94}. QED corrections with soft photon exponentiation to unstable $W$ pair production are implemented in Monte Carlo generators.\textsuperscript{95} One of the specific problems in the theoretical description of the production process for $W$ bosons is the presence of the width term in the $W$ propagator, which violates gauge invariance, yielding gauge-dependent am-
plitudes. As a solution, it has been proposed\textsuperscript{96} to take into account also the imaginary part in the $W W \gamma$ vertex from the light fermion triangle loops. This prescription is in accordance with gauge invariance and cures the Ward identities between 2- and 3-point functions involving $W^\pm$ and $\gamma$. This scheme can be extended to incorporating the whole set of fermion loop contributions at the one-loop level in the double- and single-resonating processes\textsuperscript{97}.

The systematic treatment of the complete radiative corrections is a task of enormous complexity. A reasonable simplification is given in terms of the double-pole approximation with two resonating $W$ bosons, the accuracy of which is estimated to be of order 0.1\% if one is not too close to the $WW$ threshold\textsuperscript{98}. The ‘factorizable corrections’, displayed in Figure 8, can be attributed either to the production of the gauge boson pair or to the subsequent decays. In the other class of ‘non-factorizable corrections’ the diagrams cannot be separated into a production process and decay processes (Figure 9). There are two recent independent calculations of the non-factorizable corrections in the double-pole approximation\textsuperscript{99,100}, with very good agreement. Their effect on the invariant mass distribution of one of the decaying $W$’s is below 1\% for energies above 180 GeV. An example is shown in Figure 10, where the single invariant-mass distribution $d\sigma/dM_1$ is displayed for the process $e^+e^- \to WW \to e^+\nu_e e^-\bar{\nu}_e$. The signatures are very similar also for other decay channels.

In the case of 4-quark final states, diagrams similar to those in Figure 9 arise, with the photon between two fermions replaced by a gluon line. Such typical non-factorizable QCD corrections are only formally analogous to the QED ones: in the soft-gluon limit, which is required to maintain the double-pole structure of the amplitude, the strong interaction becomes non-perturbative and can thus not be dealt with in terms of Feynman diagrams. This ‘colour reconnection’ leads to a distortion of the individual hadronic systems from separated $W$ decays and can at present be treated only with the help of hadronization models. It yields the dominant systematic error in the $W$ mass reconstruction from 4-jet final

states and is mainly responsible for the limited accuracy of about 40 MeV in the $W$-mass measurement at LEP.

Production of single-$W$ resonances occurs as a Drell–Yan process $qq' \rightarrow W \rightarrow \ell^+\nu\ell^-$ in hadron collisions. Run II of the upgraded Tevatron will provide precision measurements of $M_W$, comparable to that at LEP or even more accurate. For this purpose the inclusion of the complete set of one-loop electroweak corrections to the resonating Drell–Yan process \(^{101,102}\) becomes necessary.

The electroweak radiative corrections to the $W$ propagator around the resonance have also been studied in \(^{103}\).

5 The Higgs sector

The minimal model with a single scalar doublet is the simplest way to implement the electroweak symmetry breaking. The experimental result that the $\rho$-parameter is very close to unity is a natural feature of models with doublets and singlets. In the standard model, the mass $M_H$ of the Higgs boson appears as the only additional parameter beyond the vector boson and fermion masses. $M_H$ cannot be predicted but has to be taken from experiment. The present lower limit (95\% C.L.) from the search at LEP \(^{104}\) is 89 GeV. Indirect determinations of $M_H$ from precision data have already been discussed in section 3. The indirect mass bounds react sensitively to small changes in the input data, which is a consequence of the logarithmic dependence of electroweak precision observables. As a general feature, it appears that the data prefer a light Higgs boson.

There are also theoretical constraints on the Higgs mass from vacuum stability and absence of a Landau pole \(^{105,106,107}\), and from lattice calculations \(^{108}\). Explicit perturbative calculations of the decay width for $H \rightarrow W^+W^-$, $ZZ$ in the large-$M_H$ limit in 2-loop order \(^{110}\) have shown that the 2-loop contribution exceeds the 1-loop term in size (same sign) for $M_H > 930$ GeV (Figure 11). This result is confirmed by the calculation of the next-to-leading order correction in the $1/N$ expansion, where the Higgs sector is treated as an $O(N)$ symmetric $\sigma$-model \(^{111}\). A similar increase of the 2-loop perturbative contribution with $M_H$ is observed for the fermionic decay \(^{112}\) $H \rightarrow f\bar{f}$, but with opposite sign leading to a cancellation of the one-loop correction for $M_H \simeq 1100$ GeV (Figure 11). The requirement of applicability of perturbation theory therefore puts a stringent upper limit on the Higgs mass. The indirect Higgs mass bounds obtained from the precision analysis show, however, that the Higgs boson is well below the mass range where the Higgs sector becomes non-perturbative. The lattice result \(^{109}\) for the bosonic Higgs decay in Figure 11 for $M_H = 727$ GeV is not far from the perturbative 2-loop result. The difference may at least partially be interpreted as missing higher-order terms.

\textbf{Figure 11: Correction factors for the Higgs decay widths $H \rightarrow VV$ ($V = W, Z$) and $H \rightarrow f\bar{f}$ in 1- and 2-loop order (from ref \(^{113}\))}

\textbf{Figure 12: Theoretical limits on the Higgs boson mass from the absence of a Landau pole and from vacuum stability (from ref \(^{107}\))}

In order to avoid unphysical negative quartic couplings from the negative top quark contribution, a lower bound on the Higgs mass is derived. The requirement that the Higgs coupling remains finite and positive up to a scale $\Lambda$ yields constraints on the Higgs mass $M_H$, which have been evaluated at the 2-loop level \(^{106,107}\). These bounds on $M_H$ are shown in Figure 12 as a function of the cut-off scale $\Lambda$ up to which the standard Higgs sector can be extrapolated, for $m_t = 175$ GeV and $\alpha_s(M_Z) = 0.118$. The allowed region is the area between the lower and
reduce the experimental error down to 40\%. The 2-loop electroweak contribution is as large as the expected experimental error. The dominating theoretical uncertainty at present is still the error in the hadronic vacuum polarization. The previous discrepancy in the contribution involving light-by-light scattering has been removed, with the consequence that this term can now be considered as established with an acceptable uncertainty.

The bands indicate the theoretical uncertainties associated with the solution of the renormalization group equations\textsuperscript{107}. It is interesting to note that the indirect determination of the Higgs mass range from electroweak precision data via radiative corrections is compatible with a value of \(M_H\) where \(\Lambda\) can extend up to the Planck scale.

6 The standard model at lower energies

6.1 The decay \(B \rightarrow X_s \gamma\)

The rare radiative decay processes \(B \rightarrow X_s \gamma\) are mediated by loop diagrams and hence represent sensitive probes of the standard model as well as of extensions such as 2-Higgs doublet models or supersymmetric models. In the standard model the next-to-leading QCD calculation for the total branching ratio has been completed\textsuperscript{114}, which together with the electroweak corrections\textsuperscript{115} yields as the present best standard model prediction (for a recent review see\textsuperscript{116}):

\[
B(B \rightarrow X_s \gamma)_{\text{theor}} = (3.29 \pm 0.33) \cdot 10^{-4}.
\]  

From the experimental side, the CLEO Collaboration has reported a new result: \(B(B \rightarrow X_s \gamma) = (3.15 \pm 0.35 \pm 0.32 \pm 0.26) \cdot 10^{-4}\); the corresponding result by ALEPH\textsuperscript{118} from \(B\) mesons produced at the \(Z\) resonance is \(B(B \rightarrow X_s \gamma) = (3.11 \pm 0.80 \pm 0.72) \cdot 10^{-4}\). The experimental results are very close to each other and agree remarkably well with the standard model prediction (36). This further confirmation of the standard model simultaneously puts stringent limits to potential New Physics beyond the standard model\textsuperscript{119}.

6.2 Muon anomalous magnetic moment

The anomalous magnetic moment of the muon,

\[
a_{\mu} = \frac{g_{\mu} - 2}{2},
\]

provides a precision test of the standard model at low energies. Within the present experimental accuracy\textsuperscript{53} of \(\Delta a_{\mu} = 840 \cdot 10^{-11}\), theory and experiment are in best agreement, but the electroweak loop corrections are still hidden in the noise. The new experiment E 821 at the Brookhaven National Laboratory\textsuperscript{120} is designed to reduce the experimental error down to \(40 \pm 10^{-11}\) and hence will become sensitive to the electroweak loop contribution.

For this reason the standard model prediction has to be known with at least comparable precision. Recent theoretical work in this direction has provided the electroweak 2-loop terms\textsuperscript{122,123} with 3-loop leading-logarithmic contributions\textsuperscript{124} and updated the contribution from the hadronic photonic vacuum polarization\textsuperscript{29,125,32,33}, which is visualized in Figure 13. The lowest data point with the smallest error\textsuperscript{34} is obtained with the help of the theory-driven QCD analysis, which has been applied also to \(\Delta a_{\text{had}}(M_Z)\) (see section 2.1).

![Figure 13: Various determinations of \(a_{\mu}^{\text{had}}\) (from ref\textsuperscript{34})](image)

The main sources of the theoretical error at present are the hadronic vacuum polarization and the light-by-light scattering mediated by quarks, as part of the 3-loop hadronic contribution\textsuperscript{126,127,128}. Table 3 contains the breakdown of \(a_{\mu}\). The hadronic part is supplemented by the higher-order \(a_3\) vacuum polarization effects\textsuperscript{129} (included in the numerical value), but it does not include the light-by-light scattering contribution, which is listed separately in the table.

The 2-loop electroweak contribution is as large as the expected experimental error. The dominating theoretical uncertainty at present is still the error in the hadronic vacuum polarization. The previous discrepancy in the contribution involving light-by-light scattering has been removed, with the consequence that this term can now be considered as established with an acceptable uncertainty.
7 Beyond the standard model

7.1 Conceptual problems

The comparison of the theoretical predictions with experimental data has confirmed the validity of the standard model in an impressive way:

- the description of the data is nearly perfect, with no significant indication for deviations;
- the quantum effects of the standard model have been established at the level of several σ;
- direct and indirect determinations of the top quark mass are compatible with each other;
- the Higgs boson mass is meanwhile also being constrained within the perturbative mass regime with the possibility that the standard model may be extrapolated up to energies around the Planck scale.

In spite of this success, the conceptual situation with the standard model is unsatisfactory for quite a few deficiencies:

- the smallness of the electroweak scale \( v \sim 246 \text{ GeV} < < M_{\text{Pl}} \) (the ‘hierarchy problem’);
- the large number of free parameters (gauge couplings, vacuum expectation value, \( M_H \), fermion masses, CKM matrix elements), which are not predicted but have to be taken from experiments;
- the pattern that occurs in the arrangement of the fermion masses;
- the missing way to connect to gravity.

It is a curiosity of the standard model that these questions will persist even after the Higgs boson will have been discovered.

7.2 Massive neutrinos

Besides the long-standing list of conceptual theoretical problems, a new perspective arises through the recent experimental results by Super-Kamiokande\(^\text{132}\) on the atmospheric neutrino anomaly, which can most easily be explained by oscillations between different \( \nu \) species, associated with neutrino masses different from zero. In the strict-minimal model, neutrinos are massless and right-handed neutrino components are absent. The evidence for massive neutrinos requires a modification of the minimal model in order to accommodate neutrinos with mass. The straightforward way to introduce mass terms is the augmentation of the fermion sector by right-handed partners \( \nu_R \); together with the familiar \( \nu_L \) these allow the presence of Dirac mass terms \( \sim m_\nu \bar{\nu} \nu \) with \( \nu = \nu_L + \nu_R \) and \( m_\nu \) as additional mass parameters, without altering the global architecture of the standard model and without spoiling the successful description of all the other electroweak phenomena. What appears unsatisfactory is the unexplained smallness of the neutrino Dirac masses, as enforced by the empirical situation. A commonly accepted elegant solution is given by the seassaw-mechanism where a lepton-number-violating Majorana mass term \( \sim M \) is introduced. Together with the Dirac mass, which is of the order of the usual charged lepton masses, a very light and a very heavy \( \nu \) component appear with the light one almost entirely left-handed, when \( M \) is of the order of the GUT scale. Candidates for specific models are Grand Unification scenarios such as the SO(10)-GUT, where \( v_R \) fits into the same 16-dimensional representation as the other fermions of a family. Hence, the appearance of small neutrino masses points towards a new high-mass scale beyond the minimal model, which may be associated with the concept of further unification of the fundamental forces.

7.3 The minimal supersymmetric standard model (MSSM)

Among the extensions of the standard model, the MSSM is the theoretically favoured scenario as the most predictive framework beyond the standard model. A definite prediction of the MSSM is the existence of a light Higgs boson with mass below \( \sim 135 \text{ GeV} \).\(^{133}\) The detection of a light Higgs boson at LEP could be a significant hint for supersymmetry.

The structure of the MSSM as a renormalizable quantum field theory allows a similarly complete calculation of the electroweak precision observables as in the standard model in terms of one Higgs mass (usually taken as the CP-odd ‘pseudoscalar’ mass \( M_A \)) and \( \tan \beta = v_2/v_1 \), together with the set of SUSY soft-breaking parameters fixing the chargino/neutralino and scalar fermion sectors. It has been known for quite some time\(^{134}\) that light non-standard Higgs bosons as well as light stop and charginos predict larger values for the ratio \( R_b \).\(^{135,137}\) Complete 1-loop calculations are available for \( \Delta r \)\(^{138}\) and for the \( Z \) observables\(^{137}\).

A possible mass splitting between \( b_L \) and \( l_L \) yields a contribution to the \( \rho \)-parameter of the same sign as the standard top term. As a universal loop contribution, it enters the quantity \( \Delta r \) and the \( Z \) boson couplings and is thus significantly constrained by the data on \( M_W \) and the leptonic widths. Recently the 2-loop \( \alpha_s \) corrections have been computed\(^{138}\), which can amount to 30% of the 1-loop \( \Delta\rho_b \).

Figure 14 displays the range of predictions for \( M_W \) in the minimal model and in the MSSM. It is thereby assumed that no direct discovery has been made at LEP 2. As can be seen, precise determinations of \( M_W \) and \( m_t \) can become decisive for the separation between the models.

As the standard model, the MSSM yields a good de-
description of the precision data. A global fit to all electroweak precision data, including the top mass measurement, shows that the $\chi^2$ of the fit is slightly better than in the standard model; but, owing to the larger numbers of parameters, the probability is about the same as for the standard model (Figure 15).

![Figure 14: The $W$ mass range in the standard model (——) and the MSSM (- - -). Bounds are from the non-observation of Higgs bosons and SUSY particles at LEP2.](image)

![Figure 15: Best fits in the SM and in the MSSM, normalized to the data. Error bars are those from data. (Updated from ref $^92$.)](image)

The virtual presence of SUSY particles in the precision observables can be exploited also in the other way of constraining the allowed range of the MSSM parameters. Since the quality of the standard model description can be achieved only for those parameter sets where the standard model with a light Higgs boson is approximated, deviations from this scenario result in a rapid decrease of the fit quality. An analysis of the precision data in this spirit can be found in ref $^{139}$.

8 Conclusions

The experimental data for tests of the standard model have achieved an impressive accuracy. In the meantime, many theoretical contributions have become available to improve and stabilize the standard model predictions and to reach a theoretical accuracy clearly better than 0.1%.

The overall agreement between theory and experiment for the entire set of the precision observables is remarkable and instructively confirms the validity of the standard model. Fluctuations of data around the predictions are within two standard deviations, with no compelling evidence for deviations. Direct and indirect determinations of the top mass are compatible, and a light Higgs boson is clearly favoured by the analysis of precision data in the standard model context, which is far below the mass range where the standard Higgs sector becomes non-perturbative.

As a consequence of the high quality performance of the standard model, any kind of New Physics can only provoke small effects, at most of the size that is set by the radiative corrections. The MSSM, mainly theoretically advocated, is competitive to the standard model in describing the data with about the same quality in global fits. Since the MSSM predicts the existence of a light Higgs boson, the detection of a Higgs at LEP could be an indication of supersymmetry. The standard model can also accommodate such a light Higgs, but with the consequence that its validity cannot be extrapolated to energies much higher than the TeV scale.
