ABSTRACT

Stationary magnetohydrodynamic (MHD) outflows from a rotating accretion disk are investigated numerically by time-dependent axisymmetric simulations. The initial magnetic field is taken to be a split-monopole poloidal field configuration frozen into the disk. The disk is treated as a perfectly conducting, time-independent density boundary \([\rho(r)]\) in Keplerian rotation. The outflow velocity from this surface is not specified but rather is determined self-consistently from the MHD equations. The temperature of the matter outflowing from the disk is small in the region where the magnetic field is inclined away from the symmetry axis \((c_s^2 \ll v_k^2)\), but relatively high \((c_s^2 \lesssim v_k^2)\) at very small radii in the disk where the magnetic field is not inclined away from the axis. We have found a large class of stationary MHD winds. Within the simulation region, the outflow accelerates from thermal velocity \((\sim c_s)\) to a much larger asymptotic poloidal flow velocity of the order of one-half \(\sqrt{GM/r_i}\) where \(M\) is the mass of the central object and \(r_i\) is the inner radius of the disk. This asymptotic velocity is much larger than the local escape speed and is larger than fast magnetosonic speed by a factor of \(\sim 1.75\). The acceleration distance for the outflow, over which the flow accelerates from \(\sim 0\) to, say, 90% of the asymptotic speed, occurs at a flow distance of about 80\(r_i\). The outflows are approximately spherical, with only small collimation within the simulation region. The collimation distance over which the flow becomes collimated (with divergence less than, say, 10°) is much larger than the size of our simulation region. Close to the disk the outflow is driven by the centrifugal force while at all larger distances the flow is driven by the magnetic force which is proportional to \(\sim -\nabla (r B_\phi)^2\), where \(B_\phi\) is the toroidal field.

Our stationary numerical solutions allow us (1) to compare the results with MHD theory of stationary flows, (2) to investigate the influence of different outer boundary conditions on the flows, and (3) to investigate the influence of the shape of the simulation region on the flows. Different comparisons were made with the theory. The ideal MHD integrals of motion (constants on flux surfaces) were calculated along magnetic field lines and were shown to be constants with accuracy 5 – 15%. Other characteristics of the numerical solutions were compared with the theory, including conditions at the Alfvén surface.

Different outer boundary conditions on the toroidal component of the magnetic field were investigated. We conclude that the commonly used “free” boundary condition on the toroidal field leads to artificial magnetic forces on the outer boundaries, which can significantly influence to the calculated flows. New outer boundary conditions are proposed and investigated which do not give artificial forces.

We show that simulated flows may depend on the shape of the simulation region. Namely, if the simulation region is elongated in the \(z\)-direction, then Mach cones on the outer cylindrical boundary may be partially directed inside the simulation region. Because of this, the boundary can have an artificial influence on the calculated flow. This effect is reduced if the computational region is approximately square or if it is spherical. Simulations of MHD outflows with an elongated computational region can lead to artificial collimation of the flow.

1. INTRODUCTION

The existence and nature of magnetohydrodynamic (MHD) outflows from an accretion disk threaded by an ordered magnetic field is a long-standing astrophysical problem. The problem has been investigated theoretically by many authors (Blandford & Payne 1982; Pudritz & Norman 1986; Sakurai 1987; Contopoulos & Van Horn 1989; Lovelace, Berk & Contopoulos 1991; Pelletier & Pudritz 1992; Künel & Ruden 1993; Cao & Spruit 1994; Contopoulos & Lovelace 1994; Contopoulos 1995; Ostriker
1997). See also reviews by Bisnovatyi-Kogan (1993) and Livio (1997). From the theory, a necessary condition for magnetically/centrifugally driven outflows is that the poloidal magnetic field at the disk’s surface be inclined away from the symmetry axis (z) at a sufficiently large angle.

However, the analytical theory makes drastic simplifications such as assuming self-similar dependences on the radial distance (r in cylindrical coordinates), or by integrating over the cross-section of the outflow. The self-similar solutions have divergences at both small and large r so that the influence of these regions is unknown.

Numerical MHD simulations are essential to establish the existence and understand the nature of magnetically/centrifugally driven outflows. Stationary and non-stationary MHD flows were investigated by Kudoh & Shibata (1995, 1997a,b) in one-dimensional (1D) simulations. These simulations allowed an investigation of outflows for a wide range of parameters. However, they supposed a fixed configuration of the poloidal magnetic field. Two-dimensional (2D) simulations of outflows from accretion disks were performed by Uchida & Shibata (1985), Shibata & Uchida (1986), Stone & Norman (1994), Matsumoto et al. (1996). These simulations led to strongly non-stationary accretion and outflows from the disk. In most of these studies, the non-stationarity of the solutions is due to the start up conditions with the disk rotating but the corona of the disk not rotating. In other cases the non-stationarity is due to the disk rotating at a significantly sub-Keplerian rate. These simulations are valuable in showing that temporary MHD outflows are possible, but the results depend strongly on the assumed initial conditions.

In order to avoid the strong dependence on initial conditions and the problems associated with following the internal dynamics of the accretion disk, we earlier proposed treating the outer, surface layers of the disk as a boundary condition (Ustyugova et al. 1995; Koldoba et al. 1996; Romanova et al. 1997; Romanova et al. 1998). This approach has been followed by others (Ouyed & Pudritz 1997; Ouyed, Pudritz & Stone 1997; Meier et al. 1997). In these simulations the “disk” represents an outer layer of the accretion disk. In actual situation, the outflowing matter will affect the disk evolution, or at least to the evolution of the surface layers of the disk. The angular momentum carried away by MHD outflows can give a disk accretion rate much larger than the viscous accretion rate of an α-disk, but the accretion speeds are typically much smaller than the free-fall speed (Lovelace, Romanova & Newman 1994; Lovelace, Newman & Romanova 1997). Thus, the disk can be treated as stationary during the formation and establishment of MHD outflows which takes place on a free-fall time scale. However, the long-time simulations of outflows including the back reaction on the disk are clearly of interest for future research.

Different initial magnetic field configurations have been assumed in earlier studies. The initial field assumed by Ouyed & Pudritz (1997) was the Cao & Spruit (1994) field which decreases slowly with radial distance on the disk’s surface. On the other hand, the initial magnetic field of Ustyugova et al. (1995) was the split-monopole field (Sakurai 1978; 1985), which decreases rapidly with radial distance on the disk surface. The temperature of matter outflowing from the disk of Ouyed & Pudritz (1997) was small, and the initial magnetic field was weak. However, Ouyed & Pudritz (1997) introduced a spectrum of turbulent Alfvén waves with a high pressure which is similar to having a high temperature corona. Thus the approach of Ouyed & Pudritz (1997) is similar to that of Ustyugova et al. (1995) where the magnetic field is weak and the coronal temperature is high. In both papers, the initial twist of the magnetic field results from the disk rotation because the corona is not rotating. This twisting of the magnetic field gives the collimation observed in both papers.

It is important to get stationary outflows using time-dependent MHD equations because the non-stationary flows may be artifacts of the initial conditions. Stationary magneto-centrifugally driven outflows for relatively low temperature of the “disk” matter were obtained in the 2D simulations by Romanova et al. (1997) for the case where the initial magnetic field was a “tapered” split monopole type field. This work found that in the stationary state the outflow was quasi-spherical with essentially no collimation within the simulation region. Close to the disk the outflow was driven by the centrifugal force while at larger distances the magnetic force was dominant.

In this work we investigate the case of a pure (that is, non-tapered) split-monopole magnetic field by axisymmetric (2D) numerical simulations. The motivation was to study MHD outflows from a relatively cold accretion disk where magnetic field lines are inclined away from the symmetry axis. To remove the influence of the region near the axis where magnetic field lines are not significantly inclined, we pushed hot matter from the disk in the small area around the axis. We compare our simulation results with the theory of stationary MHD flows. Further, we use our stationary simulation flows to investigate the influence of outer boundary conditions. Our earlier study (Romanova et al. 1997) showed that some simple outer boundary conditions on the toroidal magnetic field can lead to artificial forces on the boundary which significantly influence the flow within the simulation region. Here, we consider in further detail the influence of outer boundary conditions on the calculated flows.

In §2 the theory of stationary MHD flows is briefly reviewed. In §3 the numerical model is presented. The influence of the outer boundary condition on the toroidal magnetic field and the shape of the computational region is analyzed in §4. In §5 we present results of simulations of stationary flows and compare them with theory. In §6 conclusions of this work are summarized.

2. THEORY OF STATIONARY MHD FLOWS

The theory of stationary, axisymmetric, ideal MHD flows was developed by Chandrasekhar (1956), Wolpert (1959), Mestel (1961), Kulikovskiy & Lyubimov (1962), and others. Under these conditions the MHD equations can be reduced to a single equation for the “flux function” \( \Psi(r, z) \) in cylindrical \((r, \phi, z)\) coordinates (Heinemann & Olbert 1978; Lovelace et al. 1986). The flux function \( \Psi \) labels flux surfaces so that \( \Psi(r, z) = \text{const} \) represents the poloidal projection of a field line. The equation for \( \Psi \) is commonly referred to as the Grad-Shafranov equation (Lovelace et al. 1986).
2.1. Integrals of Motion

For axisymmetric conditions the flow field can be written as \( \mathbf{v} = \mathbf{v}_p + \mathbf{v}_e \mathbf{e}_\theta \) where \( \mathbf{v}_p \) is the poloidal \((r, z)\) component, \( \mathbf{v}_e = \omega r > 0 \) is the toroidal component, and \( \mathbf{e}_\theta \) is the unit toroidal vector. Similarly, the magnetic field can be written as \( \mathbf{B} = \mathbf{B}_p + B_e \mathbf{e}_\theta \). The ideal MHD equations then imply that certain quantities are constants on any given flux surface \( \Psi(r, z) = \text{const} \) or equivalently they are constants along any given stream line or a given magnetic field line. These integrals are functions of \( \Psi \) (see for example Lovelace et al. 1986).

\[
\nabla \cdot \left( \frac{\rho \mathbf{v}_p}{\rho} \right) = 0 ,
\]

\[
\nabla \cdot \left( \rho \mathbf{v}_e \right) = 0 .
\]

2.2. Physical Sense of Integrals of Motion

To clarify the physical sense of the integrals of motion, it is useful to derive the fluxes of mass, angular momentum (about the \(z\)-axis), and energy. The corresponding conservation laws for stationary conditions are

\[
\nabla \cdot \left( \frac{\rho \mathbf{v}_p}{\rho} \right) = 0 ,
\]

\[
\nabla \cdot \left[ \rho \mathbf{v}_p \left( \frac{\mathbf{v}_e^2}{2} + \frac{\mathbf{B}^2}{4\pi \rho} + w + \Phi \right) - \frac{\mathbf{B}_p (\mathbf{v} \cdot \mathbf{B})}{4\pi} \right] = 0 .
\]

Because \( \mathbf{v}_p \parallel \mathbf{B}_p \), the vector flux densities are directed along the field lines. Consider the fluxes through an annular region with surface area element \( dS \). The matter flux through the axisymmetric surface \( S \) extending out from the \(z\)-axis is

\[
\mathcal{F}_M = \int_S dS \cdot \rho \mathbf{v}_p = \frac{1}{4\pi} \int_S dS \cdot \mathbf{B}_p \mathbf{K}(\Psi) ,
\]

where we took into account the integral (1). \( dS \cdot \mathbf{B}_p \) is the magnetic flux through the annular region bounded by flux surfaces \( \Psi \) and \( \Psi + d\Psi \). Thus we can change from space integration to integration over \( \Psi \). Because \( B_r = -(1/r) \partial \Psi / \partial z \) and \( B_z = (1/r) \partial \Psi / \partial r \), we have

\[
\mathcal{F}_M(\Psi) = \frac{1}{2} \int_0^\Psi d\Psi K(\Psi') ,
\]

where \( \Psi = 0 \) corresponds to the \(z\)-axis. Similarly,

\[
\mathcal{F}_L(\Psi) = \int_0^\Psi d\Psi' \Lambda(\Psi') K(\Psi') ,
\]

\[
\mathcal{F}_E(\Psi) = \int_0^\Psi d\Psi' \left[ \left( \frac{\mathbf{v}^2}{2} + \frac{\mathbf{B}^2}{4\pi \rho} + w + \Phi \right) - \frac{\mathbf{B}_p (\mathbf{v} \cdot \mathbf{B})}{4\pi} \right]
\]

Thus, \( K d\Psi/2 \) is the matter flux between the flux surfaces separated by \( d\Psi \), \( AKd\Psi/2 \) is the angular momentum flux, and \( (E + \Lambda)Kd\Psi/2 \) is the energy flux. Note that \( \Lambda(\Psi) \) is specific angular momentum carried along the magnetic field line \( \Psi = \text{const} \), \( E(\Psi) + \Lambda(\Psi) \) is the specific energy, and \( \Omega(\Psi) \) is the angular velocity of the disk at the point where the magnetic field line or flux surface \( \Psi = \text{const} \) intersects the disk (for \( |\mathbf{v}_p| \to 0 \) at the disk).

2.3. Conditions at the Alfvén Surface

Conditions at the Alfvén surface are known to be important for the global properties of MHD flows (Weber & Davis 1967). Equations (2) and (3) constitute a linear system of equations for \( \omega \) and \( B_\phi \). The determinant of this system is zero if \( K^2 = 4\pi \rho \). Under this condition a solution exists if \( \Lambda = r^2 \Omega \) (Weber & Davis 1967) which corresponds to \( \mathbf{v}_p = \mathbf{B}_p / \sqrt{3\pi \rho} = \mathbf{v}_A \). This is the condition which defines the Alfvén surface. Figure 1 shows a possible field line \( \Psi = \text{const} \) and Alfvén surface \( A \). The radius at which this field line intersects the disk is \( r_A(\Psi) \). The radius at which it crosses the Alfvén surface is \( r_A(\Psi) \). The density at this point on the Alfvén surface is \( \rho_A(\Psi) \). Thus,
$\rho_A(\Psi) = K^2(\Psi)/4\pi$, \quad $r_A^2(\Psi) = \Lambda(\Psi)/\Omega(\Psi)$.

Equations (2) and (3) give

$$\omega = \Omega \frac{1 - \rho A r_A^2/\rho r^2}{1 - \rho A/\rho},$$

(15)

$$B_\phi = r\Omega \sqrt{4\pi \rho A} \frac{1 - r_A^2/r^2}{1 - \rho A/\rho}.$$  

(16)

Taking into account (14) - (16), one can express the fluxes of mass, angular momentum and energy, using only the values of physical quantities on the Alfvén surface:

$$\mathcal{F}_M(\Psi) = \int_0^\Psi d\Psi' \sqrt{\pi \rho A},$$

(17)

$$\mathcal{F}_L(\Psi) = \int_0^\Psi d\Psi' \sqrt{\pi \rho A} \Omega r_A^2,$$

(18)

$$\mathcal{F}_E(\Psi) = \int_0^\Psi d\Psi' \sqrt{\pi \rho A} \left(E + \Omega^2 r_A^2\right).$$

(19)

2.4. Forces

For understanding the plasma acceleration, we project the different forces onto the poloidal magnetic field lines. As mentioned, in a stationary state, matter flows along the poloidal magnetic field lines. The acceleration in the poloidal $(r, z)$ plane is

$$(v_p \cdot \nabla)v_p + v_\phi(e_\phi \cdot \nabla)(v_\phi e_\phi).$$

(20)

The last term represents the centrifugal acceleration $-(v_\phi^2/r)e_\phi = -r\omega^2 e_\phi$. To get the force per unit mass along a magnetic field line, we multiply the Euler equation by a unit vector $\mathbf{b}$ parallel to $\mathbf{B}_p$. This gives

$$f = \omega^2 r \sin \theta \left(-\frac{1}{\rho} \frac{\partial p}{\partial s} - \frac{\partial \Phi}{\partial s} + \frac{1}{4\pi \rho} \mathbf{b} \cdot [\nabla \times \mathbf{B}]\right),$$

(21)

where $\theta$ is the inclination angle of the field line to the $z$-axis. The final term of (21) is the projection of the magnetic force in the direction of $\mathbf{b}$, which can be transformed to

$$f_M = \frac{1}{4\pi \rho} \mathbf{b} \cdot [\nabla \times \mathbf{B}] = -\frac{1}{8\pi \rho r^2} \frac{\partial (r B_\phi)^2}{\partial s},$$

which is useful for understanding our results.

When magnetic field lines are inclined outward, away from the symmetry axis, the gravitational force $f_G = \partial \Phi/\partial s$ opposes the outflow of matter from the disk. If the matter is relatively cold then the pressure gradient force $f_p = -(1/\rho)(\partial p/\partial s)$ is unimportant. Then matter can be accelerated outward by the centrifugal force $f_c = \omega^2 r \sin \theta$ and/or the magnetic force $f_M$. This determines the driving mechanisms of the outflow, centrifugal and/or magnetic. The centrifugal force always acts to accelerate matter outward if the distance between magnetic field line and the axis increases. Consider the direction of the magnetic force. Note that the lines on which $r B_\phi = \text{const}$ are also poloidal current-density lines; that is, $\mathbf{j}_p = -(e_\phi/r) \times \nabla (r B_\phi)$ so that $\mathbf{j}_p \cdot \nabla (r B_\phi) = 0$. Consider a configuration of magnetic field line $\Psi = \text{const}$ and a line of current-density $\mathbf{j}_p$ as shown in Figure 2. The poloidal component of the magnetic force $\propto -\nabla (r B_\phi)^2$ is perpendicular to the current-density $\mathbf{j}_p$ and is shown on Figure 2 by arrows. Projection of this force onto the poloidal magnetic field shows that the force pushes matter upward near the disk (lower part of the region), and pushes matter downward farther from the disk (upper part of the region). The $\phi$-component of the magnetic force $\propto \mathbf{j}_p \times \mathbf{B}_p$ acts in the direction of the disk rotation and leads to unwinding of the magnetic field line close to the disk and leads to unwinding of magnetic field line farther from the disk.
shows examples where two magnetic field lines $\Psi$ are negligible. On the right-hand side, only the first term is important for $\rho \gg r_g$. Thus, the curvature of magnetic field lines in the region $r \gg r_A$ is determined by the gradient $(rB_\phi)^2$. Figure 3 shows examples where two magnetic field lines $\Psi_1$ and $\Psi_2$ cross the line $rB_\phi = \text{const}$. Again, the magnetic force $\mathbf{F} = -\nabla(rB_\phi)^2$ acts in the direction perpendicular to the current-density $j_p$. Here, we are interested in the projection of this force onto a poloidal magnetic field line. From the figure one can see that the magnetic force acts to “collimate” the magnetic field line $\Psi_1$ and “anticollimate” the field line $\Psi_2$.

Thus, magnetic and centrifugal forces may both accelerate matter, but this depends on the configuration of magnetic field and current-density lines.

### 2.5. Collimation

Consider now the collimation of the flow. From equation (6), taking into account that $\cos \theta = \partial r / \partial n$, we have

$$
(v_p^2 - v_{Ap}^2) \frac{\partial \theta}{\partial s} = -\frac{1}{8\pi \rho^2} \frac{\partial}{\partial n} (rB_\phi)^2 + \frac{\cos \theta v_p^2}{r} - \frac{1}{\rho} \frac{\partial}{\partial n} \left( p + \frac{B_{\phi}^2}{8\pi} \right) - \frac{\partial \Phi}{\partial n}. \tag{22}
$$

At large distances from the Alfvén surface $r \gg r_A$, the density $\rho \ll \rho_A$, but values $\rho v^2$ and $v_p^2$ remain finite (Heyvaerts and Norman 1989). Then $v_{Ap}^2 = (\rho/\rho_A)^2 v_p^2 \ll v_p^2$, so that the second term on the left-hand side of (22) is negligible. On the right-hand side, only the first term is important for $r \gg r_A$. Then, equation (22) simplifies to

$$
v_p^2 \frac{\partial \theta}{\partial s} = -\frac{1}{8\pi \rho v^2} \frac{\partial}{\partial n} (rB_\phi)^2. \tag{23}
$$

Thus, the curvature of magnetic field lines in the region $r \gg r_A$ is determined by the gradient $(rB_\phi)^2$. Figure 3 shows examples where two magnetic field lines $\Psi_1$ and $\Psi_2$ cross the line $rB_\phi = \text{const}$. Again, the magnetic force $\mathbf{F} = -\nabla(rB_\phi)^2$ acts in the direction perpendicular to the current-density $j_p$. Here, we are interested in the projection of this force onto a poloidal magnetic field line. From the figure one can see that the magnetic force acts to “collimate” the magnetic field line $\Psi_1$ and “anticollimate” the field line $\Psi_2$.

### 3. NUMERICAL SIMULATIONS OF MHD OUTFLOWS

For our time-dependent simulations of axisymmetric flows of an ideal plasma in a gravitational field the equations are

$$
\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho v) = 0, \tag{24}
$$

$$
\frac{\partial (\rho v)}{\partial t} + \nabla \cdot (\rho v v) = \rho \mathbf{g}, \tag{25}
$$

$$
\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (v \times \mathbf{B}) = 0, \tag{26}
$$

$$
\frac{\partial \rho S}{\partial t} + \nabla \cdot (\rho S v) = 0. \tag{27}
$$

Here, $S$ is entropy, $T_{jk} = \rho v_j v_k + \rho \delta_{jk} + (\mathbf{B}^2 \delta_{jk}/2 - \mathbf{B}_j \mathbf{B}_k)/(4\pi)$; is the stress tensor; $\mathbf{g} = -\nabla \Phi$ is the gravitational acceleration; and $\Phi$ is the gravitational potential of the central object.

The energy equation (27) is written in conservative form. From (24) and (27), one also has

$$
\frac{\partial \rho S}{\partial t} + \nabla \cdot (\rho f(S) v) = 0, \tag{28}
$$

for any continuous function $f(S)$. We take the equation of state of state to be $p = (\gamma - 1)\rho e$, where $e$ is specific internal energy, and $\gamma = \text{const}$. In the present work $\gamma = 5/3$. We take $f(S) = p/\rho^\gamma$, because the right-hand side depends only on the entropy. We solve the system of equations (24)-(26) and (28) numerically.

The central object of mass $M$ is at the center of our coordinate system. The disk is located at $z = 0$ and is treated as a perfectly conducting surface rotating with Keplerian velocity $v_K(r)$. The gravitational acceleration $\mathbf{g}$ diverges as $r \to 0$, but of course the presence of a star or black hole changes this dependence. Instead of including the finite size of the central object, the gravitational potential is smoothed close to the origin, $\Phi = -GM/(r^2 + z^2 + r_h^2)^{3/2}$.
where \( r_1 \) is the smoothing radius. The value \( r_1 \) is always much smaller than the size of the computational region. For this smoothed potential, the Keplerian velocity (for \( z = 0 \)) becomes

\[
\nu_K = r \sqrt{GM/(r^2 + r_1^2)^{3/4}}.
\]

Our results do not depend significantly on \( r_1 \) because the main part of the outflow occurs from the inclined magnetic field in the region of the disk where \( r \gg r_1 \).

3.1. Numerical Method

Equations (24) - (26) and (28) were solved with our Godunov type numerical code (Koldoba et al. 1992; Koldoba & Ustyugova 1994; Ustyugova et al. 1995). The code is based on the ideas of Roe (1986) for hydrodynamics and the related ideas of Brio & Wu (1988) for MHD. This type of TVD numerical scheme has also been developed and investigated by others (for example, Ryu, Jones & Frank 1995). The code has passed a number of essential tests (Koldoba et al. 1992; Koldoba & Ustyugova 1994) which are analogous to those described by Ryu et al. (1995). Compared with our earlier applications of this code (Ustyugova et al. 1995; Koldoba et al. 1996), a number of improvements have been made, including a procedure for guaranteeing that \( \nabla \cdot \mathbf{B} = 0 \). To satisfy the condition \( \nabla \cdot \mathbf{B} = 0 \), we projected the calculated magnetic field to the sub-space of solenoidal functions \( \mathbf{B} \) at each time step. We introduced the function \( \Psi \), which satisfies the equation

\[
\left[ r \frac{\partial}{\partial r} \left( \frac{1}{r} \frac{\partial}{\partial r} \right) + \frac{\partial^2}{\partial z^2} \right] \Psi = - r \left( \frac{\partial B_r}{\partial z} - \frac{\partial B_z}{\partial r} \right).
\]

Then the magnetic field \( \mathbf{B} \) was calculated for which \( \nabla \cdot \mathbf{B} = 0 \). A similar method was used by Ryu et al. (1995).

Most of the simulations were done on a grid with \( N_r \times N_z \) points in cylindrical coordinates. For the calculations on an approximately square region we used an inhomogeneous grid with \( 100 \times 100 \) points while for the axially elongated region we used a homogeneous grid with \( 50 \times 200 \) points. We also did a smaller number of simulations using spherical coordinates \((R, \theta, \phi)\) and a grid \( N_R \times N_\theta = 100 \times 50 \).

3.2. Initial Conditions

The motivation for this work was the study of stationary MHD flows. Hence it may appear that the initial conditions are unimportant. However, in practice, an unfavorable choice of initial conditions can lead to an essentially longer stage of transition to stationary state, or even worse, stationary flows may never be reached. The region right above the disk is the most important, because the velocity distribution near the disk determines the number of boundary conditions (the flow may be subsonic or supersonic). Also, the physical parameters, such as density and magnetic field, are largest just above the disk. Hence, we worked more carefully on the equilibrium at small values of \( z \). At large \( z \), approximate equilibrium in the \( z \)-direction was sufficient, because the magnetic field, which is dominant in the corona, stabilizes matter against the violent movements. The expressions given below are found to be useful initial conditions which give a smooth start up of the outflows.

The initial conditions are arranged as follows. The disk and corona are considered to be threaded by a poloidal magnetic field of monopole type (Sakurai 1987), \( \mathbf{B}_p = Q_{z} (\mathbf{R} - \mathbf{R}_Q)/|\mathbf{R} - \mathbf{R}_Q|^3 \), where \( Q = B_0 h^2 \) is the “charge” of the monopole, \( \mathbf{R}_Q \) is the position vector of the monopole located on the symmetry axis at a distance \( h \) below the disk.

The temperature on the disk surface, which is proportional to the square of (isothermal) sound speed \( c_T^2 = p/\rho \), was taken to have the dependence

\[
c_T^2 = \Phi(r) \left( \kappa + \kappa_\chi e^{-r^2/\kappa^2} \right),
\]

where \( \kappa \) and \( \kappa_\chi \) are parameters, \( r_T \) is a characteristic radius inside of which the disk is relatively hot. For specificity we take \( r_T = 2r_1 \). For \( r \gg r_T, c_T^2/\Phi(r, 0) \approx \kappa \); that is, the sound speed is constant fraction of the Keplerian velocity in the region where we expect centrifugally/magnetically driven outflows from the disk. The term in (29) with \( \kappa_\chi \) increases the temperature in the region near the axis, where magnetic or centrifugal outflows are not expected. For actual conditions, this part of the

Fig. 3.— The figure shows a poloidal current-density line \( j_p \) on which \( rB_\phi = \text{const} \) and two poloidal field lines. On the field line \( \Psi_1 \), the magnetic force \( \propto -\nabla(rB_\phi)^2 \) acts to give collimation while for the field line \( \Psi_2 \) the force acts to “anti-collimate” the flow.
flow may be connected with the star or black hole (Livio 1997).

We supposed that the initial temperature of the corona is a function only of \( r \), so that the equation (29) is the initial condition for the entire computational region. Also, we supposed that in \( z \)-direction the gravitational force is balanced by the pressure gradient,

\[
\frac{1}{\rho} \frac{\partial p}{\partial z} = \frac{c_T^2(r)}{\rho} \frac{\partial \rho}{\partial z} = - \frac{\partial \Phi}{\partial z} .
\]

The solution of this equation is

\[
p(r, z) = p_d(r) \exp \left[ \frac{\Phi(r, 0) - \Phi(r, z)}{c_T^2} \right],
\]

where \( p_d(r) \) is the pressure on the disk surface, and \( \Phi(r, 0) \) is the gravitational potential on the disk.

In the initial state, the surface of the disk is in equilibrium. We suppose that the gravitational force on the disk surface is compensated by the centrifugal force, while the matter pressure gradient in \( r \)-direction is compensated by the magnetic force. That is, on the disk (\( z = 0 \)),

\[
\frac{\partial p_d}{\partial r} + \frac{1}{8\pi r^2} \frac{\partial (rB_\phi)}{\partial r} = 0 .
\]

Solution of this equation for pressure on the disk \( p_d(r) \) and current \( I_d(r) = (c/2)rB_\phi |_{z=0} \) flowing through a circular area of radius \( r \) on the disk can be written as

\[
p_d(r) = \frac{B_0^2}{8\pi} \cos^n \theta ,
\]

\[
I_d(r) = \frac{cB_0 h}{2} \left[ \frac{n}{n-2} (1-\cos^n \theta) - (1-\cos^2 \theta) \right]^{1/2},
\]

where \( \cos \theta = h/(h^2 + r^2)^{1/2} \), with \( h = \text{const} \), and \( \theta \) is the inclination of magnetic field line to the axis of rotation. This gave us possibility to find initial azimuthal magnetic field along the disk, \( B_\phi(r) = 2I_d(r)/cr \). Close to the disk, \( rB_\phi \) is approximately constant along a magnetic field line.

The three components of the initial magnetic field on the disk are shown in Figure 4.

To escape rapid twisting of the magnetic field due to the difference between the azimuthal velocities of the disk and the corona, we supposed that the corona initially rotates with an angular velocity which is constant on cylinders \( r = \text{const} \) and equal to \( v_K/r \) of the disk. As a result of this rotation the corona is not in equilibrium in the \( r \)-direction. However, this lack of initial equilibrium does not disrupt the evolution of outflows from the disk, and it does not affect the final stationary states where the flow reaches equilibrium.

### 3.3. Boundary Conditions

The lower boundary of our simulation region is the disk which is perfectly conducting and rotates at the Keplerian rate. Thus the tangential component of the electric field in the system of coordinates rotating with the disk is zero,

\[
[(\mathbf{v} - \mathbf{v}_d) \times \mathbf{B}]_{r, \phi} = 0 ,
\]

at \( z = 0 \), where \( \mathbf{v}_d = v_{K} e_\phi \) and \( \mathbf{v} \) is the fluid velocity just above the disk. This condition means that in this system of coordinates the poloidal velocity is parallel to the poloidal magnetic field at \( z = 0 \).

The magnetic field is frozen into the disk so that \( B_z = B_{dz}(r) \), where \( B_{dz} \) is a given function of \( r \) and is determined by the \( z \)-component of the initial monopole magnetic field. Notice that the two other field components, \( B_r \) and \( B_\phi \), are not fixed on the disk and change with time so as to satisfy the MHD equations in the computational region.

We suppose that the density and entropy on the disk surface are fixed, \( \rho = \rho_d(r) \), \( S = S_d(r) \) with \( \rho_d(r) \) and \( S_d(r) \) given functions of \( r \) which follow from equations (29) and (31).

Note that in the present work, the velocity of outflow from the disk is a free variable. This is different from our earlier work (Ustyugova et al. 1995). When the velocity of outflow from the disk is less than the slow magnetosonic speed, then the number of boundary conditions we have...
is sufficient. However, if the outflow velocity is super slow magnetosonic, then there should be an additional boundary condition. Because we do not have this additional boundary condition, we suppose that the amplitudes of the corresponding outgoing waves are equal to zero. This is equivalent to the fact that we use the values of calculated parameters in the cells just above the disk.

On the $z$-axis, all fluxes normal to this axis are equal to zero. On the outer boundaries, $r = R_{\text{max}}$ or $z = Z_{\text{max}}$, the “free” boundary conditions $\partial F_j/\partial n = 0$ were used for all variables excluding $B_\phi$. Here, $\partial /\partial n$ is the derivative perpendicular to the boundary, $F_j = \{ \rho, f(S), v_r, v_\phi, v_z, B_r, B_z, \}$.

Our earlier simulation study (Romanova et al. 1997) showed that the condition $\partial B_\phi/\partial n = 0$ can lead to unphysical results. The outer boundary condition on $B_\phi$ is considered in detail in §4.

4. INFLUENCE OF BOUNDARY CONDITIONS ON FLOW

If the process of outflow formation is strongly non-stationary, then the problem of the influence of outer boundary conditions may not appear. This is because it is difficult to separate the influence of boundary conditions from effects connected with non-stationarity. However, when the flow goes to a steady-state, we observed that the stationary flow pattern can depend on the imposed outer boundary conditions and in some cases on the shape of the simulation region.

It is important to eliminate the influence of boundary conditions. It is possible, if (1) the flow is supersonic (super fast magnetosonic) and it is perpendicular to the outer boundaries (then information flows out of the simulation region), or (2) the correct boundary conditions are chosen by some method. The first condition cannot be realized during the stage of establishing of the flow, because initially, the flow is subsonic. If the flow is supersonic, but is not perpendicular to the boundary, then the Mach cones may be partially directed inside the simulation region and even supersonic flow may influence the flow inside the region. The orientation of the Mach cones depends in general on the shape of simulation region.

The second condition can be realized only in some approximation. The “best” outer boundary conditions are those which influence only the vicinity of the boundaries and not the central part of the simulation region. This involves all flow variables, but we will discuss only the outer boundary condition on $B_\phi$, because we found that this condition had the strongest influence on the calculated flows.

The final flow may depend on both the Mach cone orientation at the boundaries (shape of the region) and on the outer boundary condition on $B_\phi$. In different situations one of these factors may be more important than the other. To separate their influence on the final flow pattern, we discuss in §4.1 simulations for a fixed simulation region, but with different outer boundary conditions on $B_\phi$. Next, in §4.2 we fixed the boundary condition on $B_\phi$, and investigated the dependence of the flow on the shape of simulation region and the Mach cones orientation at the outer boundaries. In §4.3 we discuss both factors.

4.1. Dependence of Flows on Outer Boundary Condition on $B_\phi$

Here, we present results of simulations for a fixed elongated simulation region $R_{\text{max}} = 50 r$, $Z_{\text{max}} = 200 r$, for three different outer boundary conditions on $B_\phi$: (1) a standard “free” boundary condition, (2) a “force-free” boundary condition, and (3) a “force-balance” boundary condition.

4.1.1. “Free” Boundary Condition

First, we performed simulations for the simplest standard “free” boundary condition on $B_\phi$, $\partial B_\phi/\partial n = 0$. We observed that this boundary condition may give an artificial force on the boundary which influences the flow within the computational region. For example, if we suppose that on the top boundary $\partial B_\phi/\partial z = 0$, then the radial component of the current-density equals to zero, $j_r = -(c/4\pi)\partial B_\phi/\partial z = 0$, which means that the poloidal current-density has only a $z$-component $j_z$. This means that the poloidal current-density $j_\phi$ is not parallel to the poloidal magnetic field $B_\phi$. Consequently, there is a force (density) $j_\phi \times B_\phi/c \neq 0$ acting in the $\phi$ direction, opposite to the rotation of the disk. Figure 5 shows the geometry.

These ‘boundary’ forces act such way that the flow never reaches a stationary state. To check this fact, and to be sure that this is not an effect of non-stationarity of our initial configuration, we did simulations for cases which went to a stationary state with other outer boundary conditions. After establishing stationarity, we substituted the outer boundary conditions on $B_\phi$ to a “free” boundary condition. We observed that the stationary state was destroyed for the reasons mentioned above. Figures 6a,b demonstrate one stage of this destruction, when the poloidal velocity decreased and became less than fast magnetosonic speed in all of the computational region. Even the fluxes of mass and other physical parameters through the boundaries are not constants in this simulation. Also, matter with magnetic flux enters the region from the right-hand side, which is due to the flow being sub-fast magnetosonic.

To avoid this artificial force, we proposed a “force-free” outer boundary condition on $B_\phi$ (Romanova et al. 1997) which we discuss in the next subsection.

4.1.2. “Force-Free” Boundary Condition

Another possibility to consider is that the toroidal component of the magnetic force is zero on the outer boundaries. That is, $j_\phi \parallel B_\phi = 0$ on the outer boundaries. We can write this condition as

$$\mathbf{B}_\phi \cdot \nabla (r B_\phi) = 0 \, .$$

We performed simulations with this boundary condition in the elongated region and observed that the flow reached a stationary state (see Figures 6 c,d). This flow has many characteristics of stationary flow. Fluxes of mass, energy, and momentum, integrated over different cross-sections, are constants. Integrals of motion along magnetic field lines are also constants. The flow is well collimated inside the simulation region (see Figures 6c, d). However, more detailed analysis (see §4.2) shows that this collimation is artificial. The “force-free” boundary condition for $B_\phi$ is superior to the “free” boundary condition, because it leads to a stationary state, but it does not give the physically correct flow. In reality, the magnetic force should not be
Then, we obtain

discussed in

tion) depends on the shape of the simulation region and is
collimation. Another possible factor (Mach cones orienta-
sign.

we put the force equal to zero, it is analogous to applica-
tion of a force equal to the real force but with the opposite
sign.

This is one of the factors which may lead to artificial
collimation. Another possible factor (Mach cones orientation) depends on the shape of the simulation region and is
discussed in §4.2.

4.1.3. “Force-Balance” Boundary Condition

As a next step for improving the outer boundary condition on \( B_\phi \), we take into account the fact that the magnetic field is not force-free and \( j_p \) is not parallel to \( B_p \). We start
from equation (16) for \( B_\phi \) and write it in the form

\[
r B_\phi = \Omega \sqrt{4\pi \rho_A} \frac{r^2 - r_A^2}{1 - \rho_A/\rho} \approx -\Omega \sqrt{4\pi \rho_A} \rho \frac{r^2}{r_A^2},
\]

(37)

where we assume that the density at the boundary is much
less than that at the Alfvén surface, \( \rho \ll \rho_A \) for \( r^2 > r_A^2 \).

Then, we obtain

\[
B_p \cdot \nabla (r B_\phi) = -\Omega \sqrt{4\pi \rho_A} B_p \cdot \nabla (\rho r^2)
\]

\[
= r B_\phi (B_p \cdot \nabla) \ln (\rho r^2) = \alpha B_r B_\phi,
\]

(38)

where we supposed that \( \rho r^2 = F(\Psi) r^\alpha \) and took into account
that \( \Omega \) and \( \rho_A \) are constants along magnetic field
lines.

Finally, we obtain the outer boundary condition as

\[
B_p \cdot \nabla (r B_\phi) = \alpha B_r B_\phi,
\]

(39)

where \( \alpha \) is a parameter. In this case we got stationary
flows which are not collimated in the simulation region
(see Figures 6e, f). Fluxes through the outer surfaces and
integrals along magnetic field lines are well conserved, as
in the case of collimated flow, described in §4.1.2.

The question arises, which boundary condition is cor-
correct, “force-free” or “force-balance” ? The “force-balance”
condition is clearly the physical condition because it does
not generate an artificial force on the boundary. How-
ever, it is more difficult to apply because there is no di-
rect method for determining the parameter \( \alpha \). It can only
be obtained iteratively using additional simulations, which
is very time consuming. Our analysis indicates that the
“force-free” boundary condition gives good results as com-
pared with those obtained using the “force-balance” con-
dition if the shape of the simulation region is not elongated
in the \( z \)-direction.

Below, we investigate different runs for “force-free”
outer boundary conditions on \( B_\phi \), but for different shapes
of the simulation region.

4.2. Dependence of Flows on Shape of Region:
Orientation of Mach Cones

We noticed empirically that results of simulations de-
depend significantly on the shape of simulation region. The
ratio between \( R_{\text{max}} \) to \( Z_{\text{max}} \) is critical. We observed that
when the region is elongated in \( z \)-direction, then the flow
has tendency to collimate. When the region is square, or
spherical, or elongated in \( r \)-direction, then the outflow
is almost spherical, that is, only slightly collimated. Here,
we present results of simulations all with “force-free” outer
boundary conditions but different shapes of the simulation
region.

First, we investigated the case where the height of the
region is the same as before, \( Z_{\text{max}} = 200r_i \), but the region
is much wider, \( R_{\text{max}} = 170r_i \). Figure 7 shows that in this

Fig. 5.— The figure demonstrates the artificial force which can appear on the top outer boundary of the simulation region in the case of a “free” boundary condition on \( B_\phi \). Here, \( B_p \) and \( j_p \) are the poloidal field and current-density (filled vectors). The hollow arrow shows the artificial force acting in the azimuthal direction.
Results of simulations using a narrow computational region $R_{\text{max}} = 50r_i$, $Z_{\text{max}} = 200r_i$ for different outer boundary conditions on $B_\phi$. Panels (a) and (b) correspond to a “free” boundary condition on $B_\phi$; (c) and (d) to a “force-free” boundary condition; and cases (e) and (f) to a “modified” boundary condition. The solid lines represent the poloidal magnetic field or flux lines $\Psi = \text{const}$, and the arrows the velocity vectors. The dashed lines in panels (b), (d) and (f) represent the level lines of the current-density. The dashed lines in panels (a), (c) and (e) represent the slow magnetosonic (lowest dashed line), the Alfvén (middle dashed line), and the fast magnetosonic (furthest from the disk) surfaces. The Mach cones are shown at the boundaries of panels (d) and (f).

In the case we got almost spherical outflow, which is very different from the well-collimated outflow in the narrow region at the same boundary conditions (Figures 6c, d).

We also performed similar simulations in spherical coordinates with $R_{\text{max}} = 170r_i$, and got similar result. The question is why the flows are so different for different shapes of the simulation region? In all cases the flow is super fast magnetosonic in most of the region. However, note that even if the flow is super fast magnetosonic, information can flow in from the boundaries to the simulation region, if the Mach cones are directed inside the simulation region.

The Mach cone projected onto the poloidal plane has a half opening angle $\varphi$ which is

$$
\tan^2 \varphi = \frac{(v_p^2 + v_A^2)(v_p^2 - v_c^2)}{(v_p^2 - c_{\text{sm}}^2)(v_p^2 - c_{\text{fm}}^2)},
$$

where $c_{\text{sm}}$ and $c_{\text{fm}}$ are the slow and fast magnetosonic velocities, respectively, which satisfy $c_{\text{sm}}^4 - c_{\text{fm}}^4(\gamma^2 + v_A^2) + c_A^2v_A^2p = 0$ (with $v_A^2 = B^2/(4\pi \rho)$ and $v_A^2p = B_p^2/(4\pi \rho)$) and $v_c \equiv v_Ap_0c_s/(\gamma^2 + c_s^2)^{1/2}$ is the “cusp” velocity (Polovin & Demutskii 1980; Lovelace et al. 1986; Bogovalov 1997).

4.3. Discussion of Boundaries

Regarding the outer boundaries, we conclude that simulated flows may depend on both the outer boundary condition on $B_\phi$ and on the shape of simulation region (the Mach cone orientation on the outer boundary). The influence of each of these factors may be different in different situations.

The orientation of the Mach cones at the boundary is not connected directly with existence and configuration of a stationary flow. However, if Mach cones are partly di-
rected inside the simulation region along part of the outer boundary, then the question arises: what is the result of this influence, and how strong is it? Our simulations shown that for a “force-free” boundary condition on $B_\phi$ the result is artificial collimation of the flow, whereas in the case of a “free” boundary condition there is destruction of a stationary flow which was arranged as an initial condition.

From comparison of cases shown in Figures 6d and 7b it is not clear that Mach cones are responsible for the collimation of the flow in the case shown in Figure 6d. In the narrow region, the magnetic field at the right-hand, outer boundary is much stronger than in the case of wide region, so that influence of the non-exact “force-free” boundary condition should be stronger in the case of a narrow region. To check this possibility, we performed simulations in a small square region with $R_{\text{max}} = 50r_i$ and $Z_{\text{max}} = 50r_i$ and found uncollimated almost spherical outflow. This indicates that the shape of the region is the most important factor affecting collimation.

Another question are evident. Why in the case of the “force-balance” boundary condition on $B_\phi$ in the elongated region do we find the physically correct stationary solution? We suggest that during establishment of the stationary flow, which may be quite violent (in spite of almost stationary initial conditions), this boundary conditions kept approach to stationarity less violent (than in the case of “force-free” boundary conditions) and kept the Mach cones directed outward most of the time. The fact that in this case a small part of the Mach cones is directed inside the region, means that some inflow of information from the outer boundary may have only a small affect on the flow.

For some purposes, such as the study of the propagation of jets, it is attractive to use a long narrow computational region. The general conclusion of this section is that a narrow region can lead to artificial collimation of the flow or invalid solutions unless special care is given to the boundary condition on $B_\phi$.

5. STATIONARY FLOWS: COMPARISONS OF SIMULATIONS WITH THEORY

Here, we describe results of simulations for a region $R_{\text{max}} = 170r_i$ and $Z_{\text{max}} = 200r_i$, with a “force-free” outer boundary condition. Simulations of the flow in the same region but with the “modified” boundary condition gave similar results.

Figure 9 shows the initial distribution on the disk of the
Keplerian velocity $v_K$, the poloidal Alfvén velocity $v_{Ap}$, and the sound speed $c_s$. Matter outflowing from the disk has a time-independent distribution of density as a function of radius. The velocity of outflow from the disk is determined by the solution of the MHD equations in the simulation region. The simulations show that in a stationary state matter just above the disk has a velocity somewhat larger than the slow magnetosonic velocity. This is in accord with the theory which indicates that the slow magnetosonic surface is located inside the disk (Lovelace, Romanova, & Contopoulos 1993).

Moving away from the disk, matter starts from a low velocity, is gradually accelerated and crosses the Alfvén and fast magnetosonic surfaces (see Figure 7a). These surfaces are almost parallel to the disk. Figure 10a shows the variation of different velocities along a representative magnetic field line, the third line away from the $z$–axis in Figure 7, on the flow distance $s$ from the disk. This field line, which we refer to as the “reference” field line, crosses the top boundary at about the midpoint of this boundary. This line is not special, but it is inclined sufficiently to the axis that magnetic/centrifugal forces are important. Figure 10a shows in particular the dependence of the poloidal velocity $v_p(s)$, which becomes larger than the Alfvén velocity $v_{Ap}$ fairly close to the disk, at $s > 10r_i$. Further, $v_p$ becomes larger than the local escape velocity $v_{esc}$ for $s > 25r_i$. At larger distances, $v_p$ becomes larger than the fast magnetosonic velocity $c_{fm}$ at $s > 40r_i$, and it approaches an asymptotic speed which is about 1.75 times $c_{fm}$ at the outer boundary of the simulation region. The poloidal velocity is parallel to the poloidal magnetic field to a good approximation in accord with the theory. Figure 10b shows the dependences of $v_p(s)$ for different field lines.

Within the simulation region, the outflow accelerates from thermal velocity to a much larger asymptotic poloidal flow velocity of the order of $0.5\sqrt{GM/r_i}$. Thus, the acceleration distance for the outflow, over which the flow accelerates from $\sim 0$ to, say, 90% of the asymptotic speed, occurs at a flow distance of about $80r_i$.

5.1. Mechanism of Acceleration

Figure 11 shows the different forces acting along the “reference” magnetic field line. The centrifugal force ($F_C$) is larger than the magnetic ($F_M$) or pressure gradient force ($F_P$) immediately above the disk $s < 10r_i$. The magnetic force is few times larger than the centrifugal force for larger distances, $s > 10r_i$. Note that the pressure gradient force is negligibly small. Thus, the main driving forces pushing matter outward are magnetic and centrifugal.

Each poloidal magnetic field line is labeled by its $\Psi$ value, which equals the magnetic flux through the circular region between the axis and the field line. $\Psi$ increases from zero on the axis to a largest value on the field line most distant from the axis. We integrated the forces to obtain the total work performed by the magnetic, centrifugal and other forces, along different field lines from the disk to the outer boundary. Figure 12 shows the dependence of this work on $\Psi$. One can see that near the axis (small $\Psi$) the main work is performed by the centrifugal force, while the magnetic force is also important. The work along the “reference” field line marked by “R” on the $\Psi$ axis, is done mainly by the magnetic force with the centrifugal force also important. Going away from the axis to larger $\Psi$ and more inclined magnetic field lines, one can see that the magnetic force is more and more important role. Note that the work done by the pressure gradient is small for all field lines.
Fig. 9.— Dependencies of velocities on $r$ (in units of $r_i$) along the disk in the stationary state, where $r_i$ is the inner radius of the disk. Here, $v_K$ is the Keplerian velocity, $c_s$ the sound speed, and $v_{Ap}$ the poloidal Alfvén velocity, measured in units of $v_i$. The point $\theta = 30^\circ$ shows the location on the disk where the poloidal magnetic field is inclined to the $z-$axis at an angle $\theta = 30^\circ$; for larger $r$ we have $\theta > 30^\circ$. We show only $r < 35 r_i$, because the magnetic field lines which start at larger $r$ are highly inclined away from the $z-$axis and also do not pass through the fast magnetosonic surface within our simulation region (see Figure 7). Inside the radius $r_T$ the disk is relatively hot (see equation 29).

5.2. Analysis of Stationarity

A first indication of stationarity is when the fluxes of mass and other physical quantities become constants in time. We observed that the fluxes of mass $F_M$, angular momentum $F_L$, and energy $F_E$ calculated through the middle of the region $z = 0.5Z_{\text{max}}$ become constants after about $t > 200 t_i$, where $t_i \equiv 2\pi r_i/v_i$, where $v_i \equiv \sqrt{GM/r_i}$, and $r_i$ is the inner radius of the disk. The time dependence of the fluxes is shown in Figure 13. We performed simulations for much longer times, $t \sim 3500 t_i$, and observed that these fluxes were accurately constants in time. Note that this time corresponds to only $t = 1.6 t_{\text{out}}$, where $t_{\text{out}} = t_i (r_{\text{out}}/r_i)^{3/2} = 2216 t_i$. This indication of stationarity is necessary, but not a sufficient sign of a valid stationary MHD flow.

Another indication of stationarity is that the poloidal velocity becomes parallel to the poloidal magnetic field. We observed, that the two vector fields become parallel to a high accuracy only after $t > t_{\text{out}}$. Figure 7a shows that the two vector fields are close to being parallel even at earlier times.

One can get more complete information about stationarity and validity of the MHD flow by comparing the theory reviewed in §3 with the simulation data. First, the integrals of the motion, $\Lambda$, $K$, $E$, $\Omega$, and $S$ (equations 4 - 8) should be constants along any magnetic field line. We checked this by numerically calculating these integrals along the “reference” magnetic field line. The calculated integrals are constants with good accuracy. For example, $|\Delta \Omega|/\Omega \leq 0.06$ and $|\Delta S|/S \leq 0.15$. Figure 14 shows variation of the integrals. Note, that the integrals are not strictly constants in the region immediately above the disk, because the grid is not fine enough in this region due to the strong gravitational force. Note that the integrals become constants as a function of $\Psi$ much later ($t \gtrsim t_{\text{out}}$) than fluxes of mass, angular momentum, and energy become constants in time.

Other comparisons of simulations with theory have been done. For example, from the theory of stationary flow it follows that fluxes of matter, angular momentum, and energy flowing inside a given flux tube should be equal to fluxes integrated over the Alfvén surface, equations (17)-(19). We calculated these integrals in two ways, using the data from our simulations. Figures 15 a, b show these integrals as a function of $\Psi$. They almost coincide in most of the region, excluding the region of large values of $\Psi$. The latter field lines have a high angle of inclination relative to the axis and do not pass through the fast magnetosonic surface. These lines are marked by the long-dashed lines on one of the curves, and by letter “f” on the $\Psi$ axis.

Figure 16 shows the $\Psi$ dependence of the ratio of the radii where a magnetic field line crosses the Alfvén surface and the disk, $\lambda = r_A(\Psi)/r_d(\Psi)$. This ratio is of interest, because the value of the angular momentum per unit mass carried by the outflowing matter can be calculated as

$$\Lambda = \Omega r_A^2 = \lambda^2 [G M r_d(\Psi)]^{1/2},$$

from equation (14). The fact that $\lambda$ is almost constant means that the specific angular momentum is proportional to $\sqrt{F_d}$ and can be estimated in this way. Specifically, $\Delta \lambda/\lambda \leq 0.13$ for field lines which cross the fast magnetosonic surface.

The fluxes of mass, energy, and angular momentum flowing out from the disk depend of course on the magnetic field strength on the disk. Figure 17 shows the dependence of the matter outflow rate on the disk magnetic field. This dependence is analogous to that derived by Kudoh & Shibata (see Kudoh & Shibata 1995, figure 2b, and Kudoh & Shibata 1997b, Figure 24b) who performed 1.5D analysis of stationary MHD flows at the fixed configuration of poloidal magnetic field.

5.3. Collimation

The stationary MHD outflows we find are approximately spherical outflows with relatively small collimation within
Fig. 10.— The top panel (a) shows the dependences of different velocities on distance $s$ measured in units of $r_i$ from the disk along the “reference” magnetic field line. The velocities are measured in units of $v_i$. The “reference” field line is the third field line away from the $z$–axis in Figure 7a. This field line crosses the top boundary about in the middle. This field line “starts” from the disk at $r \approx 6r_i$ where it has an angle $\theta \approx 28^\circ$ relative to the $z$–axis. Here, $v_p$ is the poloidal velocity along the field line and $v_\perp$ is the poloidal velocity perpendicular to the field line. Also, $v_{Ap}$ is the poloidal Alfvén velocity, $c_{fm}$ is the fast magnetosonic velocity, and $v_{esc}$ is the local escape velocity. The bottom panel (b) shows the dependences of $v_p(s)$ for different field lines identified by the number of the field line counted away from the $z$–axis in Figure 7a.

Fig. 11.— Forces acting along the “reference” field line. $M$ is the magnetic force, $C$ the centrifugal force, $P$ the pressure gradient force, and $G$ the gravitational force. The distance $s$ is measured in units of $r_i$. The scale for forces is arbitrary.

the simulation region. Thus, the collimation distance over
Fig. 12.— Work done by the different forces along different field lines from the disk to the outer boundary. Each field line is labeled by its value of $\Psi$. The field line corresponding to our “reference” line is marked “r,” and the “diagonal” field line which goes through the top right corner of the simulation region is marked “d.” The point “f” is the largest radius at which the flow goes through the fast magnetosonic surface. The letters $M$, $C$, $P$, and $G$ stand for magnetic, centrifugal, pressure gradient, and gravity.

Fig. 13.— Fluxes of mass $F_M$, angular momentum $F_L$, and energy $F_E$ across the area $z = 0$ as a function of time. Time is measured in units of $t_{\text{out}} \approx 2200t_i$, where $t_i \equiv 2\pi r_i/v_i$, where $r_i$ is the inner radius of the disk.

which the flow becomes collimated (with divergence less than, say, $10^\circ$) is much larger than the size of our simulation region. Figure 18 shows the dependence of the angle between the poloidal field direction and the $z$–axis on the distance along the “reference” magnetic field line ($\theta_1$) and along the “diagonal” field line which goes through the top right corner of the simulation region ($\theta_2$). Both angles are relatively large (> $30^\circ$) near the disk and then gradually decrease at larger distances $s$ along the field line. This means that some collimation occurs near the disk but decreases at larger distances. The angle $\theta_1$ for the “reference” field line changes from $35^\circ$ at the disk to $18^\circ$ at the top boundary where the angle of the position vector from the origin to the $z$–axis is about $20.5^\circ$. The angle $\theta_2$ for the “diagonal” field changes from $49^\circ$ at the disk to $31^\circ$ at the top boundary where the angle of the position vector from the origin to the $z$–axis is about $39^\circ$.

An important question is whether the outflow becomes collimated at large distances to form a cylindrical jet parallel to the rotation axis, or it continues as a wind without collimation. To obtain information on this question, we calculated the derivatives $\partial \theta / \partial s$ along magnetic field lines as also shown in Figure 18. For both the “reference” and the diagonal field lines the derivatives decrease and become very small at the outer boundary. It appears that the derivatives continue to decrease, which would mean that the collimation decreases and goes to zero. (The turns at the ends of the lines are connected with boundaries and do not represent a real collimation effect.) However, the present study does not rule out the possible magnetic collimation of the flow at much larger distances. Separate simulations in a much larger region are needed to answer this important question.

Earlier, Sakurai (1987) obtained stationary flow solutions for a split-monopole magnetic field and found flows with very gradual collimation at large distances from the origin. Our results are similar in this respect to those of Sakurai. However, it is not clear that the flows will magnetically collimate to cylinders as predicted by Heyvaerts & Norman (1989). Simulations on a much larger region...
Fig. 14.— Numerically calculated “integrals of the motion” (equations 1-5) as a function of distance $s$ along the “reference” magnetic field line. In ideal MHD, the integrals should be strictly constant. In this plot the scale is such that the maximum of the $E$ integral is unity. The other curves have been displaced downward for clarity.

Fig. 15.— Panel (a) shows the matter flux and panel (b) the angular momentum flux as a function of $\Psi$ calculated in two ways. The solid line shows the integrals calculated using equations (11) and (12). The dashed line shows the integrals calculated on the Alfvén surface using equations (17) and (18). Points “$r$,” “$d$,” and “$f$” on the horizontal axis are the same as in Figure 12. The long-dashed line shows the region of strongly inclined field lines which do not cross the fast magnetosonic surface. These field lines are separated from the other field lines by “$f$” on the $\Psi$ axis.

are needed to answer this question. It is important to note that analytic, self-similar solutions for outflows for cases of very gradually decreasing poloidal magnetic field in the disk (unlike the present split-monopole field) show magnetic collimation with increasing distance $z$ from the origin (Contopoulos & Lovelace 1994, Contopoulos 1995; Ostriker 1997). Further, note that outflows may be collimated hydrodynamically by the pressure of surrounding, ambient matter (Lovelace, Berk, & Contopoulos 1991; Frank & Mellema 1996, Mellema & Frank...
Fig. 16.— The ratio $\lambda = r_A(\Psi)/r_d(\Psi)$ as a function of $\Psi$. Points “r,” “d,” and “f” are the same as in Figures 12.

Fig. 17.— The dependence of matter flux from the disk on the ratio $v_{Ap}/v_K$ evaluated at the point $r = r_i$. Here, we changed only the magnitude of the magnetic field $B_p$ while all other parameters were kept the same. The triangle indicates the main case of the paper while the circles were obtained from different runs. The dashed line is simply a curve through the points.

Fig. 18.— The figure shows the dependence of the angle $\theta$ between the poloidal magnetic field and the $z$-axis as a function of distance $s$ along the field line. The dependence of the derivatives $\partial \theta / \partial s$ is also shown. The label “1” indicates our “reference” magnetic field line and “2” the “diagonal” field line discussed in the text.

1998). This mechanism of collimation needs a separate numerical investigation.

It is of interest to compare the present results on collimation with those of our earlier studies, Ustyugova et al. (1995) and Romanova et al. (1997). Ustyugova et al. (1995) introduced the treatment of the disk as a boundary
condition and found non-stationary but well-collimated outflows. Ustyugova et al. considered outflows from a hot accretion disk where the sound speed $c_s \lesssim v_K$ and a weak magnetic field $B_0^2 < v_K^2$ on the disk surface. For such conditions, the main force driving the outflow is the matter pressure gradient while the magnetic force is smaller. Also, Ustyugova et al. (1995) used non-equilibrium initial conditions where the rotation of the disk was started at $t = 0$ with the corona of the disk not rotating. These conditions led to the formation of a strong toroidal magnetic field (by the winding up of the poloidal field) and a strong outward propagating torsional Alfvén wave. The fact, that Alfvén velocity was much smaller than Keplerian velocity allowed the build up of the toroidal field which in turn gave strong collimation of the outflow. At later times in the simulation, the twist of the field relaxed, but the matter pressure force continued to push matter along the collimated magnetic field lines. Thus, the Ustyugova et al. (1995) flows are essentially different from the stationary outflows discussed in this paper where the dominate driving forces are magnetic and centrifugal with the matter pressure force negligible.

Romanova et al. (1997) was the first simulation study to obtain stationary magneto-centrifugally driven outflows with relatively small matter pressure force. The initial poloidal magnetic field was a “tapered” monopole configuration. The outflows were found to be uncollimated and are therefore similar to those discussed in this paper for the split monopole initial field.

5.4. Illustrative Physical Values

Here, we discuss physical values for parameters for the case of MHD outflows from the disk around a young star. The mass of the star is considered to be $M = M_\odot \approx 2 \times 10^{33}$ gm, and the inner radius of the disk is $r_i = 10^{11}$ cm, which may be somewhat larger than the star’s radius. The magnetic field threading the accretion disk may arise from the “shearing off” and opening of the intrinsic stellar field at the Keplerian velocity which allowed the build up of the toroidal field which in turn gave strong collimation of the outflow. At later times in the simulation, the twist of the field relaxed, but the matter pressure force continued to push matter along the collimated magnetic field lines. Thus, the Ustyugova et al. (1995) flows are essentially different from the stationary outflows discussed in this paper where the dominate driving forces are magnetic and centrifugal with the matter pressure force negligible.

Romanova et al. (1997) was the first simulation study to obtain stationary magneto-centrifugally driven outflows with relatively small matter pressure force. The initial poloidal magnetic field was a “tapered” monopole configuration. The outflows were found to be uncollimated and are therefore similar to those discussed in this paper for the split monopole initial field.

We have studied MHD outflows from a rotating, conducting accretion disk using axisymmetric simulations. The disk was treated as a boundary condition, and the initial poloidal magnetic field was taken to be a split-monopole. The main conclusions of this work are:

1. In many different runs we observed the formation of stationary MHD outflows from the disk. Close to the disk the main driving force is the centrifugal force. At larger distances the main driving force is the magnetic force $\propto -\nabla (r B_\phi)^2$. The pressure gradient force is much smaller than these forces and it has no significant role in driving the outflows.

2. For the considered conditions, the slow magnetosonic surface lies inside the disk. Above the disk, the flow accelerates and passes through the Alfvén and fast magnetosonic surfaces, which are almost parallel to the disk. Within the simulation region, the outflow accelerates from thermal velocity ($\sim c_s$) to a much larger asymptotic poloidal flow velocity of the order of $0.5 \sqrt{GM/r_i}$, where $M$ is the mass of the central object, and $r_i$ is the inner radius of the disk. This asymptotic velocity is much larger than the local escape speed and is larger than fast magnetosonic speed by a factor of $\sim 1.75$. The acceleration distance for the outflow, over which the flow accelerates from $\sim 0$ to say 90% of the asymptotic speed, occurs at a flow distance $\sim 80 r_i$.

3. The outflow is only slightly collimated within the simulation region. The collimation distance for the outflow, over which the flow becomes collimated (with divergence less than say 10°), is much larger than the size of our simulation region. This “poor” collimation is similar to that found in our earlier work (Romanova et al. 1997) using a different initial magnetic field and is qualitatively similar to the very gradual collimation found by Sakurai (1987). MHD simulations using much larger computational regions are needed to determine the collimation of the outflow at large distances. Further, separate simulations are also needed to study collimating influence of an external medium (Lovelace et al. 1991, Mellema & Frank 1998).
4. The stationarity of the MHD flows was checked in a number of ways, including comparisons of simulation results with predictions of theory of stationary axisymmetric flows. We found that: (a) Fluxes of mass, angular momentum, and energy across the surface \( z = 0.5Z_{\text{max}} \) become independent of time with high precision at early times of simulations \( t < 0.1 t_{\text{out}} \), where \( t_{\text{out}} \approx 2200 \), and \( t_1 = 2\pi r_1/\sqrt{GM/r_1} \). (b) Integrals of the motion become constants on flux surfaces with accuracy 5% – 15% for \( t > t_{\text{out}} \). (c) Vectors of poloidal velocity are parallel to those of the poloidal magnetic field lines to a high accuracy.

5. Different outer boundary conditions on the toroidal magnetic field \( B_\phi \) were investigated. We analyzed simulation results using and found that collimation of the jet and other characteristics of the flow depend critically on the outer boundary condition on \( B_\phi \) (as well as the shape of the simulation region as discussed below). We observed that the outer “free” boundary condition on \( B_\phi \) leads to an artificial force which can give apparent magnetic collimation of the flow. “Force-free” and “force-balance” outer boundary conditions were also investigated. The “force-free” outer boundary condition was found to give valid flow solutions if the simulation region is not narrow in \( r \)-direction (compared with \( z \)-direction).

6. The question of the optimum shape of simulation region was investigated. We have shown that if region is narrow in \( r \)-direction, then an essential part of the Mach cones on the outer boundaries may be directed towards the inside of the computational region. This can lead to the influence of the boundary on the calculated flow and to artificial collimation.
