We investigate the chiral phase transition at nonzero temperature $T$ and baryon-chemical potential $\mu_B$ within the framework of the linear sigma model and the Nambu–Jona-Lasinio model. For small bare quark masses we find in both models a smooth crossover transition for nonzero $T$ and $\mu_B = 0$ and a first order transition for $T = 0$ and nonzero $\mu_B$. We calculate explicitly the first order phase transition line and spinodal lines in the $(T, \mu_B)$ plane. As expected they all end in a critical point. We find that, in the linear sigma model, the sigma mass goes to zero at the critical point. This is in contrast to the NJL model, where the sigma mass, as defined in the random phase approximation, does not vanish. We also compute the adiabatic lines in the $(T, \mu_B)$ plane. Within the models studied here, the critical point does not serve as a “focusing” point in the adiabatic expansion.
I. INTRODUCTION

Chiral symmetry is spontaneously broken in the QCD vacuum. Lattice QCD simulations at nonzero temperature $T$ and zero baryon-chemical potential $\mu_B$ indicate that chiral symmetry is restored above a temperature $T \sim 150$ MeV [1]. Such temperatures are believed to be created in nuclear collisions at ultra-relativistic energies. Consequently, a phase where chiral symmetry is transiently restored may be formed in these collisions. The subsequent expansion cools the system and takes it to the final hadronic state, where chiral symmetry is again spontaneously broken.

It is important to determine the order of the chiral transition, as this influences the dynamical evolution of the system. For instance, it has been shown that a first order transition may lead to a deflagration wave and to a “stall” in the expansion of the system [2]. It has also been shown that a first order transition in rapidly expanding matter may manifest itself by strong non-statistical fluctuations due to droplet formation [3]. In the case of strong supercooling it may lead to large fluctuations due to spinodal decomposition [4,5]. In a second order phase transition one may expect the appearance of critical fluctuations due to a large correlation length [6]. Experimentally, large-acceptance detectors are now able to measure average as well as event-by-event observables, which in principle allow to distinguish between scenarios with a first order, a second order, or merely a crossover type of a phase transition.

Theoretically, the QCD phase diagram in the $(T,\mu_B)$ plane has recently received much attention (see [6–9]). QCD with $N_f = 2$ flavors of massless quarks has a global $SU(2)_L \times SU(2)_R$ symmetry. This symmetry is spontaneously broken in the QCD vacuum, such that the order parameter $\phi^{ij} \sim \langle \bar{q}^i_L q^j_R \rangle$ acquires a non-vanishing expectation value, where $q^i$ is the quark field ($i, j$ are the flavor indices). At zero baryon-chemical potential, the effective theory for this order parameter is the same as the $O(4)$ model which has a second order phase transition. Therefore, by universality arguments [10], the chiral transition in $N_f = 2$ QCD is likely to be of second order at $\mu_B = 0$. Nonzero quark masses introduce a term
in the QCD Lagrangian which explicitly breaks chiral symmetry. Then, the second order transition becomes crossover.

At nonzero baryon-chemical potential, it is more difficult to infer the order of the chiral transition from universality arguments [11]. One commonly resorts to phenomenological models to describe the chiral transition in this case. Depending on the parameters of these models, they predict a first order, a second order, or a crossover transition. However, if there is a second order phase transition for $\mu_B = 0$ and nonzero $T$ and a first order transition for small $T$ and nonzero $\mu_B$, then there exists a tricritical point in the $(T, \mu_B)$ plane where the line of first order phase transitions meets the line of second order phase transitions. For nonzero quark masses, this tricritical point becomes a critical point.

It has recently been proposed [6] that this point could lead to interesting signatures in heavy-ion collisions at intermediate energies, if the evolution went through or close to this critical point. At this point, susceptibilities (e.g. the heat capacity) diverge, and the order parameter field becomes massless and consequently fluctuates strongly, which could be detected in event-by-event observables.

In this paper we investigate the thermodynamics of two popular models of chiral dynamics, the linear sigma model coupled to quarks [12], and the Nambu–Jona-Lasinio (NJL) model [13]. Both models are tuned to reproduce correctly properties of the physical vacuum. Our goal is to study the chiral transition and to verify the existence of the critical point at nonzero chemical potential and temperature. We also study the behavior of isentropes in the vicinity of the phase transition line in the $(T, \mu_B)$ plane. These results can then be used in dynamical simulations to confront the predictions of [2–6] with experimental data.

The structure of the paper is as follows. In Section II we study the thermodynamics of the linear sigma model coupled to quarks. This part of the paper is an extension of our previous study in ref. [14]. In Section III we do the same for the NJL model. Section IV presents numerical results. We conclude in Section V with a summary of our results. Our units are $\hbar = c = k_B = 1$, the metric tensor is $g^{\mu\nu} = \text{diag}(+, -, -, -)$. 
II. THERMODYNAMICS OF THE LINEAR SIGMA MODEL

The Lagrangian of the linear sigma model with quark degrees of freedom reads

\[ \mathcal{L} = \bar{q} \left[ i \gamma^\mu \partial_\mu - g (\sigma + i \gamma_5 \vec{\tau} \cdot \vec{\pi}) \right] q + \frac{1}{2} \left( \partial_\mu \sigma \partial^\mu \sigma + \partial_\mu \vec{\pi} \cdot \partial^\mu \vec{\pi} \right) - U(\sigma, \vec{\pi}) , \]  

(1)

where the potential is

\[ U(\sigma, \vec{\pi}) = \frac{\lambda^2}{4} (\sigma^2 + \vec{\pi}^2 - v^2)^2 - H\sigma . \]  

(2)

Here \( q \) is the light quark field \( q = (u, d) \). The scalar field \( \sigma \) and the pion field \( \vec{\pi} = (\pi_1, \pi_2, \pi_3) \) together form a chiral field \( \Phi = (\sigma, \vec{\pi}) \). This Lagrangian is invariant under chiral \( SU(2)_L \times SU(2)_R \) transformations if the explicit symmetry breaking term \( H\sigma \) is zero. The parameters of the Lagrangian are usually chosen such that the chiral symmetry is spontaneously broken in the vacuum and the expectation values of the meson fields are \( \langle \sigma \rangle = f_\pi \) and \( \langle \vec{\pi} \rangle = 0 \), where \( f_\pi = 93 \text{ MeV} \) is the pion decay constant. The constant \( H \) is fixed by the PCAC relation which gives \( H = f_\pi m_\pi^2 \), where \( m_\pi = 138 \text{ MeV} \) is the pion mass. Then one finds \( v^2 = f_\pi^2 - m_\pi^2 / \lambda^2 \).

The coupling constant \( \lambda^2 \) is determined by the sigma mass, \( m_\sigma^2 = 2\lambda^2 f_\pi^2 + m_\pi^2 \), which we set to 600 MeV, yielding \( \lambda^2 \approx 20 \). The coupling constant \( g \) is usually fixed by the requirement that the constituent quark mass in vacuum, \( M_{\text{vac}} = gf_\pi \), is about 1/3 of the nucleon mass, which gives \( g \approx 3.3 \).

Let us consider a system of quarks and antiquarks in thermodynamical equilibrium at temperature \( T \) and quark chemical potential \( \mu \equiv \mu_B / 3 \). The grand partition function reads:

\[ Z = \text{Tr} \exp \left[ - (\hat{\mathcal{H}} - \mu \hat{\mathcal{N}}) / T \right] = \int \mathcal{D}\bar{q} \mathcal{D}q \mathcal{D}\sigma \mathcal{D}\vec{\pi} \exp \left[ \int_x \left( \mathcal{L} + \mu \bar{q} \gamma^0 q \right) \right] . \]  

(3)

Here \( \int_x \equiv i \int_0^{1/T} dt V d^3x \), where \( V \) is the volume of the system. We adopt the mean-field approximation, replacing \( \sigma \) and \( \vec{\pi} \) in the exponent by their expectation values. Then, up to an overall normalization factor:

\[ Z = \exp \left( - \frac{VU}{T} \right) \int \mathcal{D}\bar{q} \mathcal{D}q \exp \left\{ \int_x \bar{q} \left[ i \gamma^\mu \partial_\mu - g (\sigma + i \gamma_5 \vec{\tau} \cdot \vec{\pi}) \right] q + \mu \bar{q} \gamma^0 q \right\} \]

\[ = \exp \left( - \frac{VU}{T} \right) \det_p \left\{ [p_\mu \gamma^\mu + \mu \gamma^0 - g (\sigma + i \gamma_5 \vec{\tau} \cdot \vec{\pi})] / T \right\} . \]  

(4)
All thermodynamical quantities can be obtained from the grand canonical potential

\[ \Omega(T, \mu) = -\frac{T \ln Z}{V} = U(\sigma, \vec{\pi}) + \Omega_{q\bar{q}}, \]  

(5)

where the quark and antiquark contribution reads:

\[ \Omega_{q\bar{q}}(T, \mu) = -\nu_q \int \frac{d^3p}{(2\pi)^3} \left\{ E + T \ln \left[ 1 + \exp \left( \frac{\mu - E}{T} \right) \right] + T \ln \left[ 1 + \exp \left( \frac{-\mu - E}{T} \right) \right] \right\}. \]  

(6)

Here, \( \nu_q = 2N_cN_f = 12 \) is the number of internal degrees of freedom of the quarks, \( N_c = 3 \), and \( E = \sqrt{p^2 + M^2} \) is the valence quark and antiquark energy. The constituent quark (antiquark) mass, \( M \), is defined to be:

\[ M^2 = g^2(\sigma^2 + \vec{\pi}^2). \]  

(7)

The divergent first term in eq. (6) comes from the negative energy states of the Dirac sea. As follows from the standard renormalization procedure it can be partly absorbed in the coupling constant \( \lambda^2 \) and the constant \( v^2 \). However, a logarithmic correction from the renormalization scale remains and is neglected in the following. Similar logarithmic terms are explicitly included in calculations within the NJL model (see below). Therefore one can use the comparison of these two models to conclude about the importance of these corrections.

After integrating eq. (6) by parts the contribution of valence quarks and antiquarks can be rewritten as

\[ P_{q\bar{q}}(T, \mu) = \frac{\nu_q}{6\pi^2} \int_0^\infty dp \frac{p^4}{E} \left[ n_q(T, \mu) + n_{\bar{q}}(T, \mu) \right], \]  

(8)

where \( n_q \) and \( n_{\bar{q}} \) are the quark and antiquark occupation numbers,

\[ n_q(T, \mu) = \frac{1}{1 + \exp[(E - \mu)/T]}, \quad n_{\bar{q}}(T, \mu) = n_q(T, -\mu). \]  

(9)

The baryon-chemical potential is determined by the net baryon density

\[ n_B = \left. \frac{1}{3} \frac{\partial \Omega}{\partial \mu} \right| = \frac{\nu_q}{6\pi^2} \int p^2 dp \left[ n_q(T, \mu) - n_{\bar{q}}(T, \mu) \right]. \]  

(10)
The net quark density is obviously \( n = 3n_B \). The values for the \( \sigma \) and \( \vec{\pi} \) fields and thereby the quark masses in eq. (7) are obtained by minimizing \( \Omega \) with respect to \( \sigma \) and \( \vec{\pi} \),

\[
\frac{\partial \Omega}{\partial \sigma} = \lambda^2 (\sigma^2 + \vec{\pi}^2 - v^2) \sigma - H + g\rho_s = 0 ,
\]

(11)

\[
\frac{\partial \Omega}{\partial \pi_i} = \lambda^2 (\sigma^2 + \vec{\pi}^2 - v^2) \pi_i + g\rho_{ps,i} = 0 .
\]

(12)

The scalar and pseudoscalar densities can be expressed as:

\[
\rho_s = \langle \bar{q}q \rangle = g\sigma\nu_q \int \frac{d^3p}{(2\pi)^3} \frac{1}{E} \left[ n_q(T, \mu) + n_{\bar{q}}(T, \mu) \right] ,
\]

(13)

\[
\vec{\rho}_{ps} = \langle \bar{q}i\gamma_5\vec{\tau}q \rangle = g\vec{\pi}\nu_q \int \frac{d^3p}{(2\pi)^3} \frac{1}{E} \left[ n_q(T, \mu) + n_{\bar{q}}(T, \mu) \right] .
\]

(14)

The minima of \( \Omega \) defined by eqs. (11), (12) correspond to the stable or metastable states of matter in thermodynamical equilibrium where the pressure is \( P = -\Omega_{\text{min}} \). The \( \sigma \) and pion masses are determined by the curvature of \( \Omega \) at the global minimum:

\[
M_\sigma^2 = \frac{\partial^2 \Omega}{\partial \sigma^2} , \quad M_{\pi_i}^2 = \frac{\partial^2 \Omega}{\partial \pi_i^2} .
\]

(15)

Explicitly they are given by the expressions

\[
M_\sigma^2 = m_\sigma^2 + \lambda^2 \left( \frac{M_\pi^2 g^2}{3} - f_\pi^2 \right)
+ g^2 \frac{\nu_q}{2\pi^2} \int dp p^2 \left[ \frac{1}{\left( E^3 \right)} \left( \frac{1}{1 + \exp([E + \mu]/T)} + \frac{1}{1 + \exp([E - \mu]/T)} \right) \right]
- \frac{M_\pi^2}{TE^2} \left( \frac{1}{2(1 + \cosh([E + \mu]/T))} + \frac{1}{2(1 + \cosh([E - \mu]/T))} \right) ,
\]

(16)

\[
M_{\pi_i}^2 = m_\pi^2 + \lambda^2 \left( \frac{M_\pi^2 g^2}{g^2} - f_\pi^2 \right)
+ g^2 \frac{\nu_q}{2\pi^2} \int dp p^2 \frac{1}{E} \left[ \frac{1}{1 + \exp([E + \mu]/T)} + \frac{1}{1 + \exp([E - \mu]/T)} \right] .
\]

(17)

Here we have set the expectation value of the pion field to zero, \( \vec{\pi} = 0 \), thus \( M^2 = g^2\sigma^2 \). This version of the sigma model was used earlier in ref. [14] for thermodynamical calculations at nonzero \( T \) and \( \mu = 0 \), and at nonzero \( \mu \) and \( T = 0 \). Some useful formulae for the case of small quark mass are given in the Appendix.
The NJL model has been widely used earlier for describing hadron properties and the chiral phase transition [15,16]. The simplest version of the model including only scalar and pseudoscalar 4-fermion interaction terms is given by the Lagrangian 1:

\[
\mathcal{L} = \bar{q} (i\gamma^\mu \partial_\mu - m_0) q + \frac{G}{2} \left[ (\bar{q}q)^2 + (\bar{q}i\gamma_5 \vec{\tau}q)^2 \right],
\]

where \( m_0 \) is the small current quark mass. At vanishing \( m_0 \) this NJL Lagrangian is invariant under chiral \( SU(2)_L \times SU(2)_R \) transformations. The coupling constant \( G \) has dimension \((\text{energy})^{-2}\), which makes the theory non-renormalizable. Therefore, a 3-momentum cutoff \( \Lambda \) is introduced to regularize divergent integrals. It defines an upper energy limit for this effective theory. Free parameters of the model are fixed to reproduce correctly the vacuum values of the pion decay constant (93 MeV), pion mass (138 MeV), and the constituent quark mass (337 MeV). Below we use the following parameters [18]: \( G = 5.496 \, \text{GeV}^{-2} \), \( m_0 = 5.5 \, \text{MeV} \), and \( \Lambda = 631 \, \text{MeV} \). With these parameters the chiral transition occurs at the temperature \( T \approx 190 \, \text{MeV} \) [16] (for \( \mu = 0 \)) which is significantly higher than in the sigma model.

The partition function for the NJL model reads:

\[
Z = \text{Tr} \exp \left[ - (\hat{\mathcal{H}} - \mu \hat{\mathcal{N}}) \right] = \int \mathcal{D}\bar{q} \mathcal{D}q \exp \left[ \int_x \left( \mathcal{L} + \mu \bar{q} \gamma^0 q \right) \right].
\]

In the mean-field approximation the Lagrangian (18) is represented in a linearized form [15,19]:

\[
\mathcal{L} = \bar{q} (i\gamma^\mu \partial_\mu - m_0) q + G \langle \bar{q}q \rangle \langle \bar{q}q \rangle - \frac{G}{2} \langle \bar{q}q \rangle^2,
\]

such that the partition function becomes

\[1\] As demonstrated in ref. [17], the inclusion of the vector-axialvector terms may change significantly the parameters of the chiral phase transition, in particular, the position of the critical point. But this does not change the qualitative conclusions of the present paper.
\[ Z = \exp \left[ - \frac{V G(\bar{q}q)^2}{T^2} \right] \det_p \left[ (p_\mu \gamma^\mu + \mu \gamma^0 - M)/T \right], \]  

where the constituent quark mass is determined from the gap equation

\[ M = m_0 - G \langle \bar{q}q \rangle. \]  

The right-hand side of this equation involves the scalar density

\[ \rho_s = \langle \bar{q}q \rangle = M \nu_q \int_{p<\Lambda} \frac{d^3p}{(2\pi)^3} \frac{1}{E} [n_q(T,\mu) + n_{\bar{q}}(T,\mu) - 1], \]  

where \( n_q \) and \( n_{\bar{q}} \) are the valence quark and antiquark occupation numbers defined in eq. (9). Here the last term in brackets gives the contribution from the Dirac sea (which corresponds to the vacuum part of the sigma model) and cannot be neglected. The rest comes from valence quarks and antiquarks similar to the sigma model (compare with eq. (13)).

From eq. (20), the grand canonical potential for the NJL model can be written as:

\[ \Omega = \frac{(M - m_0)^2}{2G} - \nu_q \int_{p<\Lambda} \frac{d^3p}{(2\pi)^3} \left\{ E + T \ln \left[ 1 + \exp \left( -\frac{E + \mu}{T} \right) \right] + T \ln \left[ 1 + \exp \left( -\frac{E - \mu}{T} \right) \right] \right\}. \]  

The minimization of \( \Omega \) with respect to \( M \) gives the gap equation (22). The expression (24) is formally identical with eq. (6) derived for the sigma model, but now the first term in curly brackets, coming from the Dirac sea, is treated explicitly after introducing the cut-off momentum \( \Lambda \). One can calculate this vacuum contribution explicitly,

\[ \Omega_{\text{vac}} = -\nu_q \int_{p<\Lambda} \frac{d^3p}{(2\pi)^3} \sqrt{p^2 + M^2} = -\nu_q \Lambda^4 \left\{ \sqrt{1 + z^2} \left( 1 + \frac{z^2}{2} \right) - \frac{z^4}{2} \ln \frac{\sqrt{1 + z^2} + 1}{z} \right\}, \]  

where \( z = M/\Lambda \). Expanding this expression in powers of \( z \) one can find contributions to \( \Omega \) of order \( M^2, M^4, \ldots \). As mentioned above, in the sigma model the vacuum terms are partly absorbed in the coefficients of the effective potential \( U(\sigma, \vec{\pi}) \). However, the logarithmic term \( M^4 \ln \frac{\Lambda}{M} \) cannot be removed in this way. Therefore, the NJL model has additional nonlinear terms in the vacuum energy which are responsible for the differences in the thermodynamic properties of the two models.
The sigma and pion masses are not as straightforward to obtain as in the linear sigma model because in the NJL model they are not represented as dynamical fields. In this model mesons are described as collective $q\bar{q}$ excitations. Their masses can be obtained from the poles of the quark-antiquark scattering amplitude which can be computed, for instance, in Random Phase Approximation (RPA) [16]. In this way, one can derive the following equations for the sigma and pion masses,

$$0 = \frac{m_0}{M} + (M_\sigma^2 - 4M^2)G I(M, M_\sigma) ,$$

$$0 = \frac{m_0}{M} + M_\pi^2 G I(M, M_\pi) .$$

The function $I(x, y)$ is the quark-antiquark propagator defined as:

$$I(x, y) = \frac{\nu_q}{2\pi^2} \mathcal{P} \int_{p<\Lambda} dp p^2 \frac{1}{E} [1 - n_q - n_{\bar{q}}] \frac{1}{E^2 - \frac{1}{4}y^2} ,$$

where $E = \sqrt{x^2 + p^2}$, and the occupation numbers $n_q, n_{\bar{q}}$ are as defined in (9). In this integral $\mathcal{P}$ means principal value.

IV. NUMERICAL RESULTS

In the case of the linear sigma model everything is determined when the gap equation (11) is solved in the $(T, \mu)$ plane, whereas in the NJL model the meson masses have to be solved for as well. Below we present results of our numerical calculations (see also Appendix).

A. Phase diagrams

We start this section with presenting in Fig. 1 the resulting phase diagrams in the $(T, \mu)$ plane calculated for the two models. The middle line corresponds to the states where the two phases co-exist in the first order phase transition. Along this line the thermodynamical potential $\Omega$ has two minima of equal depth separated by a potential barrier which height grows towards lower temperatures. At the critical point C the barrier disappears and the
transition is of second order. The other lines in Fig. 1 are spinodal lines which constrain the regions of spinodal instability where \((\frac{\partial n}{\partial \mu})_T < 0\). Information about the timescales of this instability can be obtained from dynamical simulations \([4,5]\).

It is instructive to plot the thermodynamic potential as a function of the order parameter for various values of \(T\) at \(\mu = 0\), and for various values of \(\mu\) at \(T = 0\). The first case is shown in Fig. 2, where the left panel is for the sigma model and the right panel for the NJL model. One clearly sees the smooth crossover of the symmetry breaking pattern in both cases. Note that the effective bag constant (the energy difference between the global minimum and the local maximum of the potential in vacuum) is about 100 MeV/fm\(^3\) in the NJL model, whereas in the sigma model it is significantly smaller, \(\simeq 60\) MeV/fm\(^3\). To a large extent this difference is responsible for the difference in the temperatures corresponding to the crossover transition: about 140 MeV in the sigma model and about 180-190 MeV in the NJL model.

In Fig. 3 the same plot is shown for \(T = 0\) and a nonzero \(\mu\). Here, one clearly observes the pattern characteristic for a first order phase transition: two minima corresponding to phases of restored and broken symmetry separated by a potential barrier. The barrier height is larger in the sigma model than in the NJL model, thus, indicating a weaker first order phase transition in the NJL model. It now follows that somewhere in between these two extremes, for some \(\mu_c\) and \(T_c\), there exists a second order phase transition (the critical point). Indeed, this point is found and shown in Fig. 1. The corresponding values are \((T_c, \mu_c) \simeq (99, 207)\) MeV in the sigma model, and \((T_c, \mu_c) \simeq (46, 332)\) MeV in the NJL model. The behavior of the thermodynamic potential at \(\mu = \mu_c\) and various \(T\) is shown in Fig. 4. One can see that the potential has only one minimum which is flattest at the critical point.

**B. Effective Masses**

Now let us consider the model predictions for the effective masses. The constituent quark mass is shown in Fig. 5 as function of \(T\) and \(\mu\). These plots, of course, show the same phase
structure as discussed above. At $\mu = 0$ in both models the quark mass falls smoothly from
the respective vacuum value and approaches zero as $T$ goes to infinity. One could define a
crossover temperature as corresponding to a steepest descent region in the variation of $M$.
This again gives a temperature of about $140 - 150$ MeV for the sigma model and about
$180 - 190$ MeV for the NJL model. At $T = 0$ and nonzero $\mu$ the constituent quark mass
shows a discontinuous behavior reflecting a first order chiral transition.

The sigma and pion masses for various $T$ and $\mu$ are shown in Figs. 6,7. In both models
the sigma mass first decreases smoothly, then rebounds and grows again at high $T$. The pion
mass does not change much at temperatures below $T_c$ but then increases rapidly, approaching
the sigma mass and signaling the restoration of chiral symmetry. As $T$ goes to infinity the
masses grow linearly with $T$. The $\mu = \mu_c$ case is especially interesting in the sigma model.
Since the sigma field is the order parameter of the chiral phase transition, its mass must
vanish at the critical point for a second order phase transition. This means that $\Omega$ has zero
curvature at this point. It is, however, not clear what the sigma mass should be at the
critical point in the NJL model where the quark condensate $\langle \bar{q}q \rangle$ is the order parameter.
Fig. 6 indeed shows that exactly at the critical point the sigma mass is zero in the sigma
model. This is not the case in the NJL model, at least within the RPA used here.

In Fig. 7 the masses are plotted as function of $\mu$ for $T = 0$ and $T = T_c$. For $T = 0$
one clearly sees discontinuities in the behavior of the masses characteristic for the first order
phase transition.

An interesting point is that, in the linear sigma model, there is no stable phase with
heavy quarks for $T = 0$, i.e., the quark mass assumes its vacuum value all the way up to
the chiral transition, and then drops to a small value in the phase where chiral symmetry
is restored (see Fig. 7). This behavior is related to the appearance of a bound state at
zero pressure. Within the linear sigma model this “abnormal” bound state was found by
Lee and Wick a long time ago [21]. Recently, it was shown in ref. [17] that a similar bound
state appears also in the NJL model. This behavior, however, depends on the value of the
coupling constant $g$ or $G$. For our choice of $g$ and $G$, this state exists in the linear sigma
model, but not in the NJL model, where there is a stable phase of heavy quarks at $T = 0$, cf. Figs. 5 and 7. In general, if the coupling constant is sufficiently large, then the attractive force between the constituent quarks becomes large enough to counterbalance the Fermi pressure, thus giving rise to a bound state. To demonstrate this we have varied the coupling constant $g$ for the sigma model within reasonable limits.

The results for the quark mass are shown in Fig. 8. It is seen that, indeed, one can change the smooth crossover for $\mu = 0$ into a first order transition by increasing the coupling constant (Fig. 8 left panel) and change the first order transition in the case of $T = 0$ into a smooth crossover. In this way a heavy quark phase comes into existence as the coupling constant is decreased and the bound state disappears (Fig. 8 right panel). An analogous investigation for the NJL model leads to similar results.

C. Adiabats

Regarding hydrodynamical simulations the entropy per baryon is an interesting quantity. One can easily calculate it using standard thermodynamic relations,

$$\frac{S}{A} = 3\frac{e + p - \mu n}{Tn},$$

where $e, p, n$ are respectively the energy density, pressure and net density of the quarks and antiquarks ($n = 3n_B$). By studying this quantity, one can check if there is a tendency towards convergence of the adiabats towards the critical point as was claimed in ref. [6]. If this was the case it would be easy to actually hit or go close to this point in a hydrodynamical evolution. Fig. 9 shows the contours of $S/A$ in the $(T, \mu)$ plane calculated in the sigma model (left) and in the NJL model (right). We actually observe a trend which is quite opposite to this expectation. It turns out that the adiabats turn away from the critical point when they hit the first order transition line and bend towards the critical point only when they come from the smooth crossover region. This is explained as follows. First, note that all adiabats terminate at zero temperature and $\mu = M_{\text{vac}}$, i.e. the $(T, \mu)$ combination corresponding to
the vacuum. The reason is that as $T \to 0$, also $S \to 0$ (by the third law of thermodynamics), therefore, for fixed $S/A$ we have to require that $n \to 0$, which is fulfilled when $\mu = M_{\text{vac}}$. For our choice of parameters, in the sigma model the point $(T, \mu) = (0, M_{\text{vac}})$ is also the endpoint of the phase transition curve at $T = 0$, since the phase transition connects the vacuum directly with the phase of restored chiral symmetry, cf. Figs. 5 and 8. For the NJL model, the endpoint of the phase transition curve is not identical with $(0, M_{\text{vac}})$ but is rather close to it. Therefore, also the adiabats which hit the phase transition curve have to bend away from the critical point and approach the endpoint of the phase transition line at $T = 0$, i.e., $T$ decreases and $\mu$ increases.

This behavior is quite opposite to the case underlying the claim in ref. [6], where the hadronization of a large number of quark and gluon degrees of freedom into relatively few pion degrees of freedom leads to the release of latent heat and consequently to a reheating (increase of $T$) through the phase transition. Remember, however, that in our case there is actually no change in the number of degrees of freedom in the two phases, only in their respective masses. Consequently, there is no “focusing” effect in the linear sigma and NJL models.

V. CONCLUSIONS

We investigated the thermodynamics of the chiral phase transition within the linear sigma model coupled to quarks and the Nambu-Jona-Lasinio model. These models have similar vacuum properties but treat the contribution of the Dirac Sea differently. In the sigma model this contribution is “renormalized out” while in the NJL model it is included explicitly up to a momentum cutoff $\Lambda$. By comparing thermodynamic properties of these two models one can check the importance of these vacuum terms. In both models, we found for small bare quark masses a smooth crossover for nonzero temperature and zero chemical potential and a first order transition for zero temperature and nonzero chemical potential. The first order phase transition line in the $(T, \mu)$ plane ended in the expected
Critical point. It has been found that the $\sigma$ mass is zero at the critical point in the sigma model whereas in the NJL model it always remains nonzero. The phase transition in the sigma model turned out to be of the liquid-gas type. This, however, depends on the coupling constant $g$ between the quarks and the chiral fields. From the comparison we conclude that the phase transition pattern is generally weaker in the NJL model than the sigma model. Certainly, it will be interesting to use both models in hydrodynamical simulations in order to confirm or disconfirm possible observable signatures of the phase transition discussed in the introduction. In particular, the sigma model which contains dynamical $\sigma$ and pion fields, would be suitable to study the long wavelength enhancement of the $\sigma$ field at the critical point. Such simulations are in progress.

ACKNOWLEDGEMENTS

O.S. thanks the Yale Relativistic Heavy Ion Group for kind hospitality and support from grant no. DE-FG02-91ER-40609. The work of Á.M. is supported by the US. Department of Energy under grant DE-FG02-87ER40328. I.N.M. thanks the Humboldt Foundation for financial support. D.H.R thanks RIKEN, BNL, and the U.S. Dept. of Energy for providing the facilities essential for the completion of this work.

APPENDIX A

In the chirally symmetric phase the constituent quark (antiquark) mass $M$ is small, it goes to zero in the chiral limit. Therefore, it is instructive to evaluate the thermodynamic potential $\Omega(T, \mu, M)$ for small $M$. In this limit $\Omega_{\bar{q}q}$ can be represented as a power series in $M$. Below we give explicit expressions for the sigma model. Taking into account that $\Omega_{\bar{q}q}$ is an even function of $M$, one can write

$$\Omega_{\bar{q}q}(T, \mu, M) = \Omega_0(T, \mu) + \frac{M^2}{2} \left( \frac{\partial^2 \Omega_{\bar{q}q}}{\partial M^2} \right)_{M=0} + ... \quad (A1)$$
Here the first term, \( \Omega_0(T, \mu) \equiv \Omega_{qq}(T, \mu, 0) \), can be easily calculated for arbitrary \( T \) and \( \mu \). The well-known result is

\[
\Omega_0(T, \mu) = -\frac{\nu_q}{2\pi^2} \left[ \frac{7\pi^4}{180} T^4 + \frac{\pi^2}{6} T^2 \mu^2 + \frac{1}{12} \mu^4 \right].
\] (A2)

The quark number and entropy densities for massless fermions are obtained by differentiating \( \Omega_0(T, \mu) \) with respect to \( \mu \) and \( T \), respectively,

\[
n = \frac{\nu_q}{6\pi^2} (\pi^2 T^2 \mu + \mu^3),
\] (A3)

\[
s = \frac{\nu_q}{6\pi^2} \left( \frac{7\pi^4}{15} T^3 + \pi^2 T \mu^2 \right).
\] (A4)

The second term in eq. (A1) differs only by a factor of \( M \) from the scalar density defined in eq. (13). A straightforward calculation gives

\[
\left( \frac{\partial^2 \Omega}{\partial M^2} \right)_{M=0} = \left( \frac{\rho_s}{M} \right)_{M=0} = \nu_q \left( \frac{T^2}{12} + \frac{\mu^2}{4\pi^2} \right). \]
\] (A5)

This can be used to estimate the pion and sigma masses at large \( T \) and/or \( \mu \). Expressing \( M^2 \) in terms of mean \( \pi \) and \( \sigma \) fields, eq. (15), and using the definition of effective masses from eq. (7), one arrives at the following asymptotic \( (M \to 0) \) expression for the pion and sigma masses

\[
M_{\pi}^2 = M_{\sigma}^2 = g^2 \nu_q \left( \frac{T^2}{12} + \frac{\mu^2}{4\pi^2} \right). \]
\] (A6)

It shows that deep in the chiral symmetric phase the pion and sigma masses are degenerate and large. At high temperatures \( (T \gg \mu) \), \( M_{\pi} = M_{\sigma} = gT \), where \( g \sim 3 \) in our calculations. Therefore, the contribution of pion and sigma excitations to the thermodynamical potential is negligible.

In case of the NJL model the above expressions are slightly modified due to the finite cut-off \( \Lambda \) in the momentum integration.

FIG. 1. The phase diagrams for the sigma model (left) and the NJL model (right) in the $(\mu, T)$ plane. The middle curve is the critical line and the outer lines are the lower and upper spinodal lines. C is the critical point.
FIG. 2. The thermodynamical potentials $\Omega$ for the sigma model (left) and the NJL model (right). For both models $\mu = 0$. The levels correspond to (starting from the top): $T = [0, 100, 135, 155, 175, 190]$ MeV for the sigma model and $T = [0, 100, 140, 170, 200, 230]$ MeV for the NJL model.

FIG. 3. The thermodynamical potentials $\Omega$ for the sigma model (left) and the NJL model (right). For both models $T = 0$. The levels correspond to (starting from the top): $\mu = [0, 225, 279, 306, 322, 345, 375]$ MeV in the sigma model, and $\mu = [0, 288, 343, 348, 35, 378, 396]$ MeV for the NJL model.
FIG. 4. The thermodynamical potentials $\Omega$ for the sigma model (left) and the NJL model (right). For the sigma model case $\mu$ is fixed to 207 MeV and the levels correspond to (starting from the top): $T = [0, 50, 75, 100, 125, 150]$ MeV. For the NJL model case $\mu$ is fixed to 332 MeV and the levels correspond to (starting from the top): $T = [0, 28, 46, 70, 105, 133]$ MeV.

FIG. 5. The constituent quark (antiquark) mass in the sigma model (left) and the NJL model (right) as function of $\mu$ and $T$. 
FIG. 6. The sigma mass (solid line) and pion mass (dashed line) in the sigma model (left) and NJL model (right) as functions of temperature for $\mu = 0$ (right pair) and for $\mu = \mu_c$ (left pair).

FIG. 7. The sigma mass (solid line) and pion mass (dashed line) in the sigma model (left) and NJL model (right) as functions of chemical potential for $T = 0$ (right pair) and for $T = T_c$ (left pair).
FIG. 8. The constituent quark (antiquark) mass as function of temperature for zero chemical potential (left) and as function of chemical potential (right) for zero temperature in the sigma model. The solid line represents the mass for $g = 4.5$, the dashed-dotted line for $g = 3.3$ and the dashed line for $g = 2.8$.

FIG. 9. The entropy per baryon number, $S/A$ for the sigma model (left) and the NJL model (right). In the sigma model the curves correspond to (from left) $S/A = [28, 21, 17, 13, 11, 9, 6, 2]$. In the NJL model the curves correspond to (from left) $S/A = [22, 16, 11, 8, 6, 5, 3, 1]$.
