We perform a fit of solar neutrino data in the framework of the two four-neutrino schemes that are compatible with the results of all neutrino oscillation experiments. These schemes allow simultaneous transitions of solar $\nu_e$’s into active $\nu_x$’s, $\nu_e$’s and sterile $\nu_s$. The data imply that the SMA solution is valid for any combination of $\nu_e \rightarrow$ active and $\nu_e \rightarrow$ sterile transitions, whereas the LMA, LOW and VO solutions disappear when $\nu_e \rightarrow \nu_s$ transitions are dominant.

Talk presented by C. Giunti at the NuFact’00 Workshop, May 22-26, 2000, Naval Postgraduate School, Monterey, California, USA.

I. INTRODUCTION: WHY FOUR-NEUTRINO MIXING?

Evidences in favor of neutrino oscillations (see [1]) have been found in solar (Homestake [2], Kamiokande [3], GALLEX [4], SAGE [5], Super-Kamiokande [6]) and atmospheric (Kamiokande, IMB, Super-Kamiokande, Soudan 2, MACRO [7]) neutrino experiments and in the LSND experiment [8]. It is rather well-known [9,10] that these three evidences require the existence of at least three small neutrino mass-squared differences ($\Delta m^2$):

\begin{align}
\Delta m_{\text{sun}}^2 &\sim 10^{-10} - 10^{-4} \text{eV}^2, \\
\Delta m_{\text{atm}}^2 &\sim 10^{-3} - 10^{-2} \text{eV}^2, \\
\Delta m_{\text{LSND}}^2 &\sim 10^{-1} - 10^0 \text{eV}^2.
\end{align}

This means that at least four light massive neutrinos must exist in nature. Following the old principle known as Occam’s razor (“pluralitas non est ponenda sine necessitate”) we assume the existence of four light massive neutrinos, that is the minimal possibility compatible with all data. In this case the left-handed components $\nu_{\alpha L}$ of the flavor neutrino fields are superpositions of the left-handed components $\nu_{\alpha k}$ ($k = 1, \ldots, 4$) of neutrino fields with definite mass $m_k$ smaller than a few eV:

$$\nu_{\alpha L} = \sum_{k=1}^{4} U^{\alpha k} \nu_{\alpha k},$$

where $U$ is a 4x4 unitary mixing matrix.

From the measurement of the invisible decay width of the Z-boson it is known that the number of light active neutrino flavors is three (see [11]), corresponding to $\nu_e$, $\nu_\mu$, and $\nu_\tau$ (active neutrinos are those taking part to standard weak interactions). This implies that the number of massive neutrinos is bigger or equal to three. If there are four massive neutrinos, in the flavor basis there is one sterile neutrino, $\nu_s$, that does not take part to standard weak interactions. For the flavor index $\alpha$ in Eq. (4) we choose the ordering $\alpha = e, s, \mu, \tau$.

Let us emphasize that four-neutrino mixing is very interesting both for theory and experiment. From the theoretical point of view the existence of a light sterile neutrino can be explained only with models far beyond the Standard Model and is thus a signal of exciting new physics. From the experimental point of view four-neutrino mixing is attractive because it allows the existence of a $\Delta m^2$ at the eV scale which generates oscillations in different channels that can be explored with high precision in short-baseline experiments. Moreover, it allows large CP-violation effects in long-baseline and $\nu$-factory experiments (see [12]). Four-neutrino mixing may also open the possibility for measurable exotic phenomena, as neutrino decay, neutrino magnetic moment, etc.

From the model-builder point of view, there seems to be no difficulty in constructing models with a light sterile neutrino (as one can convince oneself with an appropriate search of the hep-ph electronic archive, resulting in too many four-neutrino models to be cited here). However, our impression is that these models are constructed with assumptions “ad hoc” in order to generate a light sterile neutrino, with the possible exception of models based on the existence of a mirror world (see [13]) and models based on the existence of large extra dimensions (see [14]), in which light neutral fermions that mix with the ordinary neutrinos seem to be naturally allowed.

Our approach is phenomenological: we extract information on four-neutrino mixing (masses and mixing angles) from the available data.

II. ALLOWED FOUR-NEUTRINO SCHEMES

The six types of four-neutrino mass spectra with three different scales of $\Delta m^2$ that can accommodate the hierarchy $\Delta m_{\text{sun}}^2 \ll \Delta m_{\text{atm}}^2 \ll \Delta m_{\text{LSND}}^2$ (see Eqs. (1)–(3)) are shown qualitatively in Fig. 1. In all these mass spectra there are two groups of close masses separated by the “LSND gap” of the order of 1 eV. The six schemes...
are divided into four schemes of class 1 (I–IV) in which there is a group of three masses separated from an isolated mass by the LSND gap, and two schemes of class 2 (A, B) in which there are two couples of close masses separated by the LSND gap. In each scheme the smallest mass-squared difference ($\Delta m^2_{ij} \equiv m_i^2 - m_j^2$) corresponds to $\Delta m^2_{21} = \Delta m^2_{\text{sun}}$, the intermediate one to $\Delta m^2_{\text{atm}}$ ($\Delta m^2_{31} \simeq \Delta m^2_{32}$ in the schemes of class 1, $\Delta m^2_{43}$ in the schemes of class 2) and the largest mass squared difference $\Delta m^2_{42} = \Delta m^2_{\text{LSND}}$ is relevant for the oscillations observed in the LSND experiment ($\Delta m^2_{12} \simeq \Delta m^2_{42} \simeq \Delta m^2_{31} \simeq \Delta m^2_{32}$ in the schemes of class 2).

It has been show that the four schemes of class 1 are disfavored by the data if also the negative results of short-baseline accelerator and reactor disappearance neutrino oscillation experiments are taken into account [15–17,9]. The reason is simple: in order to explain solar and atmospheric neutrino oscillations, including matter effects, in the framework of the two four-neutrino schemes A and B has been presented in Ref. [18]. In the next section we present the results of a fit of solar neutrino data [19].

III. FIT OF SOLAR NEUTRINO DATA

In the framework of the two four-neutrino schemes A and B, solar neutrino oscillations depend on only one mass-squared difference, $\Delta m^2_{\text{sun}}$, but there are several degrees of freedom coming from the $4 \times 4$ mixing matrix, that can be parameterized in terms of six mixing angles and three CP-violating phases (three additional CP-violating phases are possible if massive neutrinos are Majorana particles, but can be neglected in the present contest because they do not have any effect in neutrino oscillations). However, the data of solar neutrino experiments together with those of short-baseline $\bar{\nu}_e$ disappearance experiments indicate that the elements $U_{e3}$ and $U_{e4}$ of the neutrino mixing matrix are very small [15,20]. This implies that two mixing angles are small and can be neglected in the study of solar (and atmospheric) neutrino oscillations [18]. Furthermore, the CP-violating phases can be neglected because their effects are washed out by the average over neutrino energy and source-detector distance. Therefore, we consider the mixing matrix $U$ in Fig. 3 [18,19], where $\vartheta_{12}, \vartheta_{23}, \vartheta_{24}, \vartheta_{34}$ are four mixing angles and $c_{ij} \equiv \cos \vartheta_{ij}$ and $s_{ij} \equiv \sin \vartheta_{ij}$. The rows and columns of the mixing matrix $U$ correspond, respectively, to the neutrino flavors $\nu_e, \nu_s, \nu_\mu, \nu_\tau$ and to the mass eigenstates $\nu_1, \nu_2, \nu_3, \nu_4$.

Since solar neutrino oscillations are generated by the mass-squared difference between $\nu_2$ and $\nu_1$ and $U_{e1} = \cos \vartheta_{12}, U_{e2} = \sin \vartheta_{12}$, the survival of solar $\nu_e$’s, $P_{\nu_e} \rightarrow \nu_e$, mainly depends on the mixing angle $\vartheta_{21}$, with the only correction due to four-neutrino mixing in the matter potential that is given by

$$V \equiv V_{CC} + \cos^2 \vartheta_{23} \cos^2 \vartheta_{24} V_{NC},$$

where $V_{CC} = \sqrt{2} G_F N_e$ and $V_{NC} = -\sqrt{2} G_F N_n/2$ are...
the usual charged-current and neutral-current potentials (see [1]).

The mixing angles \( \theta_{23} \) and \( \theta_{24} \) determine the relative amount of transitions into sterile \( \nu_s \) or active \( \nu_\mu \) and \( \nu_\tau \) (that cannot be distinguished in solar neutrino experiments, because their matter potential and their interaction in the detectors are equal, due only to neutral-current weak interactions). The active/sterile ratio and solar neutrino oscillations in general do not depend on the mixing angle \( \theta_{34} \), that contribute only to the different mixings of \( \nu_s \) and \( \nu_\tau \). Indeed, the mixing of \( \nu_s \) with \( \nu_1 \) and \( \nu_2 \) depends only on \( \theta_{12} \) and the product \( \cos \theta_{23} \cos \theta_{34} \). Moreover, instead of \( \nu_\mu \) and \( \nu_\tau \), one can consider the linear combinations

\[
\begin{pmatrix}
\nu_a \\
\nu_b
\end{pmatrix} = \begin{pmatrix}
-\sin \theta & -\cos \theta \\
\cos \theta & -\sin \theta
\end{pmatrix} \begin{pmatrix}
\nu_1 \\
\nu_2
\end{pmatrix},
\]

with \(\tan \theta = \tan \theta_{24}/\tan \theta_{23} \). The mixing of \( \nu_a \) and \( \nu_b \) with \( \nu_1 \) and \( \nu_2 \) is given by \( U_{a1} = -s_{12} \sqrt{1 - c_{23}^2 c_{24}^2}, \quad U_{a2} = c_{12} \sqrt{1 - c_{23}^2 c_{24}^2}, \quad U_{b1} = U_{b2} = 0 \). Therefore, the oscillations of solar neutrinos depend only on \( \theta_{12} \) and the product \( \cos \theta_{23} \cos \theta_{34} \). If \( 0 < \cos \theta_{23} \cos \theta_{24} < 1 \), solar \( \nu_e \)'s can transform simultaneously into sterile neutrinos and in the linear combination \( \nu_a \) of active \( \nu_\mu \) and \( \nu_\tau \), with the limiting cases of pure two-generation \( \nu_e \to \nu_a \) transitions if \( \cos \theta_{23} \cos \theta_{24} = 0 \) (\( U_{a1} = U_{a2} = 0, \quad U_{a1} = -s_{12} \cos \theta_{12}, \quad U_{a2} = \cos \theta_{12} \)), and pure two-generation \( \nu_e \to \nu_s \) transitions if \( \cos \theta_{23} \cos \theta_{24} = 1 \) (\( U_{a1} = -s_{12} \cos \theta_{12}, \quad U_{a2} = s_{12} \cos \theta_{12} \) and \( U_{a1} = U_{a2} = 0 \)).

Since the mixing of \( \nu_\tau \) with \( \nu_1 \) and \( \nu_2 \) is equal to the one in the case of two-generations (with the mixing angle \( \theta_{12} \)), the mixing of \( \nu_s \) with \( \nu_1 \) and \( \nu_2 \) is equal to the one in the case of two-generations times \( \cos \theta_{23} \cos \theta_{24} \) and the mixing of \( \nu_s \) with \( \nu_1 \) and \( \nu_2 \) is equal to the one in the case of two-generations times \( \sqrt{1 - \cos^2 \theta_{23} \cos^2 \theta_{24}} \), it is clear that in the general case of simultaneous \( \nu_e \to \nu_a \) and \( \nu_s \to \nu_a \) oscillations the corresponding transition probabilities are given by

\[
P_{\nu_e \to \nu_a} = \cos^2 \theta_{23} \cos^2 \theta_{24} (1 - P_{\nu_s \to \nu_a}),
\]

\[
P_{\nu_s \to \nu_a} = (1 - \cos^2 \theta_{23} \cos^2 \theta_{24}) (1 - P_{\nu_e \to \nu_a}).
\]

These expressions satisfy the relation of probability conservation \( P_{\nu_e \to \nu_s} + P_{\nu_s \to \nu_e} + P_{\nu_e \to \nu_a} = 1 \).

We calculated the survival probability \( P_{\nu_e \to \nu_e} \) in the range \( 10^{-11} \text{eV}^2 \leq \Delta m_{21}^2 \leq 10^{-3} \text{eV}^2 \), \( 10^{-4} \leq \tan^2 \theta_{12} \leq 10 \) and \( 0 \leq \cos^2 \theta_{23} \cos^2 \theta_{24} \leq 1 \), taking into account matter effects for \( 10^{-8} \text{eV}^2 \leq \Delta m_{24}^2 \leq 10^{-3} \text{eV}^2 \) and the possible regeneration of \( \nu_e \)'s when the flux of solar neutrinos crosses the Earth (for details see Ref. [19]).

In order to calculate the allowed regions for the parameters \( \Delta m_{21}^2, \tan^2 \theta_{12} \) and \( c_{23}^2 c_{24}^2 \), we have used data on the total event rates measured in the Chlorine experiment at Homestake [2], in the two Gallium experiments GALLEX [4] and SAGE [5] and in the water Cherenkov detectors Kamiokande [3] and Super-Kamiokande [6] shown in Table I. We used also the zenith angle distribution of the events and the electron recoil energy spectrum measured in the Super-Kamiokande experiment (825-day data sample) [6]. For the calculation of the theoretical expectations we use the BP98 standard solar model of Ref. [21].

The calculation of the theoretical rates, the statistical treatment of the data and the results of different fits of rates only, rates and zenith angle distribution, rates and recoil electron energy spectrum are described in Ref. [19]. Here we present only the result of the global \( \chi^2 \) fit of all data.

Figure 4 shows the allowed regions at 90% and 99% CL in the \( \tan^2 \theta_{12} - \Delta m_{21}^2 \) plane for \( c_{23}^2 c_{24}^2 = 0, 0.2, 0.4, 0.5, 0.71 \), that we calculated in the following way. We computed for a grid of points in the three-dimensional \( \tan^2 \theta_{12}, \Delta m_{21}^2, c_{23}^2 c_{24}^2 \) parameter space the expected values of the observables and with those and the corresponding uncertainties we constructed the function \( \chi^2(\tan^2 \theta_{12}, \Delta m_{21}^2, c_{23}^2 c_{24}^2) \). We found its minimum, \( \chi^2_{\text{min}} \), in the full three-dimensional space considering as a unique framework both MSW and vacuum oscillations.

The allowed three-dimensional regions for a given CL are then defined as the set of points satisfying the condition

\[
\chi^2(\tan^2 \theta_{12}, \Delta m_{12}^2, c_{23}^2 c_{24}^2) - \chi^2_{\text{min}} \leq \Delta \chi^2(\text{CL, 3 dof})
\]

where \( \Delta \chi^2(\text{CL, 3 dof}) = 6.25, 11.36 \) for CL=90%, 99%, respectively. In Fig. 4 we plotted the sections of such volumes in the \( \tan^2 \theta_{12}, \Delta m_{21}^2 \) plane for six selected values of \( c_{23}^2 c_{24}^2 \).

The global minimum of \( \chi^2 \), \( \chi^2_{\text{min}} = 28.8 \), with 23 degrees of freedom corresponding to 28 data points (4 rates plus 6 Super-Kamiokande zenith-angle bins plus 18 Super-Kamiokande energy spectrum bins) minus 2 normalization factors (for the Super-Kamiokande zenith-angle and energy spectrum data) minus 3 fitted parameters, lies in the LMA region for \( \sin^2 \theta_{12} \leq 0.71 \), consistent with pure two-generation oscillations.
However, as one can see from Fig 5, the χ² of the best-fit point in the LMA, LOW and VO regions rises steeply when cos²θ₂₃ cos²θ₂₄ is increased. Therefore, the 99% CL LMA, LOW and VO regions disappear for c²₂₃c²₂₄ ≃ 0.78, 0.70, 0.83, respectively. For values of c²₂₃c²₂₄ close to one, corresponding to almost pure two-generations νₑ → νₛ transitions, only the SMA region is allowed. This is expected, because only the SMA solution is allowed in the two-generation νₑ → νₛ fit of solar data (see [22]). Notice, however, that the statistical analysis is different: in the two-generation picture the pure νₑ→active and νₑ→sterile cases are analyzed separately, whereas in the four-neutrino picture they are taken into account simultaneously in a consistent scheme that allows to calculate the allowed regions with the prescription given in Eq. (8). We think that the agreement between the results of the analyses with two and four neutrinos indicate that the physical conclusions are quite robust.

The disappearance of the LMA and LOW regions for values of c²₂₃c²₂₄ close to one is due to the following reason. Unlike active neutrinos which lead to events in the water Cherenkov detectors by interacting via neutral current with the electrons, sterile neutrinos do not contribute to the Kamiokande and Super–Kamiokande event rates. Therefore a larger survival probability for ⁸B neutrinos is needed to accommodate the measured rates. As a consequence a larger contribution from ⁸B neutrinos to the Chlorine and Gallium experiments is expected, so that the small measured rate in Chlorine can only be accommodated if less ⁷Be neutrinos are present in the flux. This is only possible in the SMA solution region, since in the LMA and LOW regions the suppression of ⁷Be neutrinos is not enough (the survival probability of νₑ’s as a function of neutrino energy is rather flat).

Figure 4 shows that the LMA region at 99% CL extends to high values of Δm²₃, even above 10⁻³ eV² for c²₂₃c²₂₄ ≲ 0.1. Since the atmospheric mass squared difference Δm² atm lies between 10⁻³ and 10⁻² eV² (see [6]), one may wonder if the solar and atmospheric mass squared differences may coincide and three massive neutrinos may be enough for the explanation of solar, atmospheric and LSND data. The answer to this question is negative, because in the high–Δm² atm part of the 99% CL LMA region the mixing angle θ₂₃ is large, 0.3 ≲ sin²(θ₂₃) ≲ 0.7, and in this case disappearance of νₑ ’s should be observed in long-baseline reactor experiments, contrary to results of the CHOOZ [23] experiment. In other words, the results of the CHOOZ experiment, that have not been taken into account in the present analysis, forbid the part of the 99% CL LMA region that extends above Δm² atm ≃ 10⁻³ eV². For this reason we cut the plots at this value.
We have considered the two four-neutrino schemes A and B in Fig. 2 that are compatible with the results of all neutrino oscillation experiments. These two schemes are completely equivalent for neutrino oscillation experiments, but have different phenomenology in $\beta$ and neutrinoless $\beta\beta$ decay experiments (see [1,24,25]).

In general the four-neutrino schemes A and B allow simultaneous transitions of solar $\nu_e$'s into active $\nu_\mu$'s, $\nu_\tau$'s and sterile $\nu_s$, as well as simultaneous transitions of atmospheric $\nu_{\mu}$'s into active $\nu_\tau$'s and sterile $\nu_s$'s.

We have fitted the data of solar neutrino experiments in terms of neutrino oscillations, that in the schemes under consideration depend on three parameters, $\Delta m^2_{21}$, $\tan^2 \theta_{12}$ and $\cos^2 \vartheta_{23} \cos^2 \vartheta_{24}$. The allowed regions of these three parameters are depicted in Fig. 4, from which one can see that the SMA region is valid for all values of $\cos^2 \vartheta_{23} \cos^2 \vartheta_{24}$ (i.e. any combination of $\nu_e$—active and $\nu_\tau$—sterile transitions), whereas the LMA, LOW and VO solutions disappear for values of $\cos^2 \vartheta_{23} \cos^2 \vartheta_{24}$ close to one, where $\nu_\mu \rightarrow \nu_\tau$ transitions are dominant.

Other authors have recently performed fits of the atmospheric neutrino data in the framework of the two four-neutrino schemes A and B [26,27]. We expect that in the future a combined fit of solar and atmospheric neutrino data will allow to constraint further the mixing of four neutrinos.

IV. CONCLUSIONS
