The decay of ortho-positronium into three photons produces a physical realization of a pure state with three-party entanglement. Its quantum correlations are analyzed using recent results on quantum information theory, looking for the final state which has the maximal amount of GHZ-like correlations. This state allows for a statistical dismissal of local realism stronger than the one obtained using any entangled state of two spin one-half particles.

I. INTRODUCTION

Entanglement or quantum correlations between many space-separated subsystems has been recognized as one of the most intrinsic properties of quantum mechanics and provides the basis for many genuine applications of quantum information theory. It is, then, quite natural to look for physical situations in which quantum entangled states are obtained. Most of the theoretical and experimental effort has so far been devoted to unveil physical realizations of quantum states describing two quantum correlated subsystems. The search for physical systems displaying clean three-party entanglement is not simple. In this paper, we shall analyze decays of particles as a natural scenario for fulfilling such a goal. More precisely, we shall show that the decay of ortho-positronium into three photons corresponds to a highly entangled state. Let us now review what entanglement can be used for and why it is interesting to look for quantum correlation between more than two particles.

In 1935 Einstein, Podolsky and Rosen [1], starting from three reasonable assumptions of locality, reality and completeness that every physical theory must satisfy, argued that quantum mechanics (QM) is an incomplete theory. They did not question quantum mechanics predictions but rather quantum mechanics interpretation [2]. Their argument was based on some inconsistencies between quantum mechanics and their local-realistic premises (LR) which appear for quantum states of bipartite systems, \(|\psi\rangle \in \mathcal{H}_d \otimes \mathcal{H}_d\). It was in 1964 when Bell [3] showed that any theory compatible with LR assumptions can not reproduce some of the statistical predictions of QM, using a gedankenexperiment proposed in [4] with two quantum correlated spin-\(\frac{1}{2}\) particles in the singlet state

\[
|s\rangle = \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle).
\]

In his derivation, as it is well-known, quantum correlations or entanglement have a crucial role. Actually, the singlet state is known to be the maximally entangled state between two particles. The conflict between LR and QM arises since the latter violates some experimentally verifiable inequalities, called Bell inequalities, that any theory according to the local-realistic assumptions ought to satisfy. It is then possible to design real experiments testing QM against LR (for a detailed discussion see [5]). Correlations of linear polarizations of pair of photons were measured in 1982 showing strong agreement with quantum mechanichs predictions and violating Bell inequalities [6]. Nowadays, Bell inequalities have been tested thoroughly in favor of QM [7].

More recently, it has been pointed out that some predictions for quantum systems having quantum correlations between more than two particles give a much stronger conflict between LR and QM than any entangled state of two particles. The maximally entangled state between three spin-\(\frac{1}{2}\) particles, the so-called GHZ (Greenberger, Horne and Zeilinger) state [8]

\[
|\text{GHZ}\rangle = \frac{1}{\sqrt{2}}(|000\rangle + |111\rangle),
\]

shows some perfect correlations incompatible with any LR model (see [2] and also [9] for more details). It is then of obvious relevance to obtain these GHZ-like correlations. Producing experimentally a GHZ state has turned out to be a real challenge yet a controlled instance has been produced in a quantum optics experiment [10].
Entanglement is then important for our basic understanding of quantum mechanics. Recent developments on quantum information have furthermore shown that it is also a powerful resource for quantum information applications. For instance, teleportation [11] uses entanglement in order to obtain surprising results which are impossible in a classical context. A lot of work has been performed trying to know how entanglement can be quantified and manipulated. Our aim in this paper consists on looking for GHZ-like correlations, which are truly three-party pure state entanglement, in the decay of ortho-positronium to three photons. The choice of this physical system has been motivated mainly by several reasons. First, decay of particles seems a very natural source of entangled particles. Indeed, positronium decay to two photons was one of the physical systems proposed long time ago as a source of two entangled space-separated particles [12]. On a different line of thought, some experiments for testing quantum mechanics have been recently proposed using correlated neutral kaons coming from the decay of a \( \phi \)-meson [13]. In the case of positronium, three entangled photons are obtained in the final state, so it offers the opportunity of analyzing a quantum state showing three-party correlations similar to other experiments in quantum optics.

The structure of the paper goes as follows. We first review the quantum states emerging in both para- and ortho-positronium decays. Then, we focus on their entanglement properties and proceed to a modern analysis of the three-photon decay state of ortho-positronium. Using techniques developed in the context of quantum information theory, we show that this state allows in principle for an experimental test of QM finer than the ones based on the use of the singlet state. We have tried to make the paper self-contained and easy to read for both particle physicists and quantum information physicists. The first ones can find a translation of some of the quantum information ideas to a well-known situation, that is, the positronium decay to photons, while the second ones can see an application of the very recent techniques obtained for three-party entangled states, which allow to design a QM vs LR test for a three-particle system in a situation different from the GHZ state.

II. POSITRONIUM DECAYS

A. Positronium properties

Let us start reminding some basic facts about positronium. Positronium corresponds to a \( e^+ e^- \) bound state. These two spin-\( \frac{1}{2} \) particles can form a state with total spin equal to zero, para-positronium (p-Ps), or equal to one, ortho-positronium (o-Ps). Depending on the value of its angular momentum, it can decay to an even or an odd number of photons as we shall see shortly.

Positronium binding energy comes from the Coulomb attraction between the electron and the positron. In the non-relativistic limit, its wave function is [14]

\[
\Psi(r) = \frac{1}{\sqrt{\pi a^3}} e^{-\frac{r}{a}} = \int \frac{d^3p}{(2\pi)^{3/2}} e^{i\vec{p} \cdot \vec{r}} \Psi(p) = \int \frac{d^3p}{(2\pi)^{3/2}} e^{i\vec{p} \cdot \vec{r}} \frac{\sqrt{8a^3}}{\pi(1 + a^2p^2)^2} ,
\]

where \( a = \frac{2}{m_e} \), i.e. twice the Bohr radius of atomic hydrogen, and \( m \) is the electron mass. Note that the wave function takes significant values only for three-momenta such that \( p \lesssim \frac{1}{a} \ll m \), which is consistent with the fact that the system is essentially non-relativistic.

The parity and charge conjugation operators are equal to

\[
U_P = (-1)^{L+1} \quad U_C = (-1)^{L+S} ,
\]

where \( L \) and \( S \) are the orbital and spin angular momentum. Positronium states are then classified according to these quantum numbers so that the ground states are \( ^1S_0 \), with \( J^{PC} = 0^- \), for the p-Ps and \( ^3S_1 + ^3D_1 \), having \( J^{PC} = 1^- \), for the o-Ps.

Positronium is an unstable bound state that can decay to photons. Since a \( n \)-photon state transforms as \( U_C |n\gamma\rangle = (-1)^n |n\gamma\rangle \) under charge conjugation, which is an exact discrete symmetry for any QED process such as the decay of positronium, we have that the ground state of p-Ps (o-Ps) decays to an even (odd) number of photons [15]. The analysis of the decay of positronium to photons can be found in a standard QED textbook [14]. Para-positronium lifetime is about 0.125 ns, while for the case of ortho-positronium the lifetime is equal to approximately 0.14 \( \mu \)s [16].

The computation of positronium decays is greatly simplified due to the following argument. The scale which controls the structure of positronium is of the order of \( |\vec{p}| \sim a m \). On the other hand, the scale for positronium annihilation is of the order of \( m \). Therefore, it is easy to prove that positronium decays are only sensitive to the value of the wave function at the origin. As a consequence, it is possible to factor out the value of the wave function from the
Para-positronium ground state decays into two photons. Because of the argument mentioned above, the determination of the two-photon state coming from the p-Ps decay is simply given by the lowest order Feynmann diagram of \(e^+e^- \rightarrow \gamma\gamma\). Since positronium is a non-relativistic particle to a very good approximation, the three-momenta of \(e^+\) and \(e^-\) are taken equal to zero, and the corresponding spinors are replaced by a two-component spin. This implies that the tree-level calculation of the annihilation of p-Ps into two photons is equal to, up to constants,

\[
\mathcal{M}(e^+e^- \rightarrow \gamma\gamma) \sim \chi^c_+M_2\chi_-,
\]

where (see [14] for more details) \(\chi_\pm\) is the two-component spinor describing the fermions, \(\chi^c = \chi^T i\sigma_2\), and \(M_2\) gives

\[
M_2 = \sum_{\text{perm}} (\tilde{\epsilon}_1^* \times \tilde{\epsilon}_2^*) \cdot \hat{k} I_{2\times2} \equiv A(\hat{k}_1, \lambda_1; \hat{k}_2, \lambda_2) I_{2\times2},
\]

where \(\tilde{\epsilon}_i^* \equiv \tilde{\epsilon}^*(\hat{k}_i, \lambda_i)\) stands for the circular polarization vector associated to the outgoing photon \(i\) and \(I_{2\times2}\) is the 2 \(\times\) 2 identity matrix. More precisely, for a photon having the three-momentum vector \(\hat{k} = |\hat{k}|\hat{k} = |\hat{k}|(\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)\), the polarization vectors can be chosen

\[
\tilde{\epsilon}(\hat{k}, \lambda) = -\frac{\lambda}{\sqrt{2}} (\cos \theta \cos \phi - i\lambda \sin \phi, \cos \theta \sin \phi + i\lambda \cos \phi, -\sin \theta),
\]

where \(\lambda = \pm 1\) and they obey

\[
\hat{k} \cdot \tilde{\epsilon}(\hat{k}, \lambda) = 0 \quad \hat{k} \times \tilde{\epsilon}(\hat{k}, \lambda) = -i\lambda \tilde{\epsilon}(\hat{k}, \lambda)
\]

\[
\tilde{\epsilon}(\hat{k}_i, \lambda_i) \cdot \tilde{\epsilon}(\hat{k}_j, \lambda_j) = -\frac{1}{2} \left(1 - \lambda_i \lambda_j \hat{k}_i \cdot \hat{k}_j\right).
\]

From the expressions of the polarizaton vectors and the three-momentum and energy conservation, it follows that the scalar term \(A\) is

\[
A(\hat{k}, \lambda_1; -\hat{k}, \lambda_2) = -\frac{i}{2}(\lambda_1 + \lambda_2),
\]

and it verifies

\[
A(\hat{k}, +1; -\hat{k}, +1) = -A(\hat{k}, -1; -\hat{k}, -1)
\]

\[
A(\hat{k}, +1; -\hat{k}, -1) = -A(\hat{k}, +1; -\hat{k}, +1) = 0.
\]

The two fermions in the para-positronium ground state are in the singlet state, \(|S=0, S_z=0\rangle = \frac{1}{\sqrt{2}} (|\frac{1}{2}, -\frac{1}{2}\rangle - | -\frac{1}{2}, \frac{1}{2}\rangle)\), and then, using the previous relations for \(A\) and (5), the two-photon state resulting of the p-Ps desintegration is

\[
|\psi_p\rangle = \frac{1}{\sqrt{2}} (|++\rangle - |--\rangle).
\]
The ground state of ortho-positronium has $J^{PC} = 1^{-+}$ and, due to the fact that charge conjugation is conserved, decays to three photons. Repeating the treatment performed for the p-Ps annihilation, the determination of the three-photon state resulting from the o-Ps decay requires the simple calculation of the tree-level Feynman diagrams corresponding to $e^+e^- \rightarrow \gamma \gamma \gamma$. Its tree-level computation gives, up to constants,

$$M(e^+e^- \rightarrow \gamma \gamma \gamma) \sim \chi^\dag M_3 \chi,$$

and the $2 \times 2$ matrix $M_3$ is equal to [14]

$$M_3 = \sum_{\text{cyclic perm.}} \left( \left( \hat{\epsilon}^*_1 \cdot \hat{\epsilon}^*_2 - \delta_1 \cdot \delta_2 \right) \hat{\epsilon}^*_1 + \left( \hat{\epsilon}^*_2 \cdot \delta_1 + \hat{\epsilon}^*_3 \cdot \delta_2 \right) \delta_1 \right) \cdot \hat{\sigma},$$

where

$$\delta_i = \hat{k}_i \times \hat{\epsilon}^*_i.$$  

Using (8) we can rewrite $M_3$ in the following way

$$M_3 = \hat{\sigma} \cdot \hat{V}(\hat{k}_1, \lambda_1; \hat{k}_2, \lambda_2; \hat{k}_3, \lambda_3),$$

where

$$\hat{V} = \left( (\lambda_1 - \lambda_2)(\lambda_2 + \lambda_3) \hat{\epsilon}^*(\hat{k}_1, \lambda_1) \left( \hat{\epsilon}^*(\hat{k}_2, \lambda_2) \cdot \hat{\epsilon}^*(\hat{k}_3, \lambda_3) \right) + \left( \lambda_2 - \lambda_3)(\lambda_3 + \lambda_1) \hat{\epsilon}^*(\hat{k}_2, \lambda_2) \left( \hat{\epsilon}^*(\hat{k}_3, \lambda_3) \cdot \hat{\epsilon}^*(\hat{k}_1, \lambda_1) \right) + \left( \lambda_3 - \lambda_1)(\lambda_1 + \lambda_2) \hat{\epsilon}^*(\hat{k}_3, \lambda_3) \left( \hat{\epsilon}^*(\hat{k}_1, \lambda_1) \cdot \hat{\epsilon}^*(\hat{k}_2, \lambda_2) \right) \right).$$

Notice that the helicity coefficient $(\lambda_1 - \lambda_2)(\lambda_2 + \lambda_3)$ for the cyclic permutations of $ijk$ explicitly enforces the vanishing of the $(+++)$ and $(−−−)$ polarizations,

$$\hat{V}(\hat{k}_1, ++; \hat{k}_2, ++; \hat{k}_3, +) = \hat{V}(\hat{k}_1, −−; \hat{k}_2, −−; \hat{k}_3, −) = 0.$$

On the other hand, the rest of structures are different from zero

$$\hat{V}(\hat{k}_1, −−; \hat{k}_2, ++; \hat{k}_3, +) = 2 \hat{\epsilon}^*(\hat{k}_1, −−)(1 − \hat{k}_2 \cdot \hat{k}_3)$$

$$\hat{V}(\hat{k}_1, ++; \hat{k}_2, −−; \hat{k}_3, −) = 2 \hat{\epsilon}^*(\hat{k}_1, ++)(1 − \hat{k}_2 \cdot \hat{k}_3),$$

and similar expressions for the other cyclic terms.

The original $e^+e^-$ in the ortho-positronium could be in any of the three triplet states. It can be shown, using (12) and (15), that when the initial positronium state is $|S=1, S_z=1\rangle = |\frac{1}{2}, \frac{1}{2}\rangle$, the decay amplitude is proportional to $V_1 + iV_2$, while the same argument gives $-V_1 + iV_2$ for $|S=1, S_z=-1\rangle = |\frac{1}{2}, -\frac{1}{2}\rangle$ and $-\sqrt{2}V_3$ for $|S=1, S_z=0\rangle = \sqrt{\frac{1}{2}}(|\frac{1}{2}, -\frac{1}{2}\rangle + | -\frac{1}{2}, \frac{1}{2}\rangle)$. Now, considering the explicit expressions of the polarization vectors (7), with $\theta = \frac{\pi}{2}$ without loss of generality, and (18), it is easy to see that the three-photon state coming from the o-Ps decay is, up to normalization,

$$|\psi_0(\hat{k}_1, \hat{k}_2, \hat{k}_3)\rangle = (1 − \hat{k}_1 \cdot \hat{k}_2)(|++−⟩ + |−−+⟩)$$

$$+(1 − \hat{k}_1 \cdot \hat{k}_3)(|++−⟩ + |−−+⟩)$$

$$+(1 − \hat{k}_2 \cdot \hat{k}_3)(|−−+⟩ + |++−⟩),$$

when the third component of the ortho-positronium spin, $S_z$, is equal to zero, and

$$|\psi_1(\hat{k}_1, \hat{k}_2, \hat{k}_3)\rangle = (1 − \hat{k}_1 \cdot \hat{k}_2)(|++−⟩ − |−−+⟩)$$

$$+(1 − \hat{k}_1 \cdot \hat{k}_3)(|++−⟩ − |−−+⟩)$$

$$+(1 − \hat{k}_2 \cdot \hat{k}_3)(|−−+⟩ − |++−⟩),$$

when $S_z = ±1$.

The final state of the o-Ps decay is, thus, an entangled state of three photons, whose quantum correlations depend on the angles among the momenta of the outgoing three photons. For the rest of the paper we will consider the first family of states ($S_z = 0$) although equivalent conclusions are valid for the second one. In the next sections we will analyze the entanglement properties of the states $|\psi_0(\hat{k}_1, \hat{k}_2, \hat{k}_3)\rangle$, using some of the quantum information techniques and comparing them to the well-known cases of the singlet and GHZ state.
The quantum correlations of the three-photon entangled state obtained from the o-Ps annihilation depend on the position of the photon detectors, i.e. on the photon directions we are going to measure. Our next aim will be to choose from the family of states given by (19) the one that, in some sense, has the maximum amount of GHZ-like correlations. In order to do this, we first need to introduce some recent results on the study of three-party entanglement.

The set of states \(|\psi_0(k_1, k_2, k_3)\rangle\) form a six-parameter dependent family in the Hilbert space \(H_2 \otimes H_2 \otimes H_2\), so that each of its components is equivalent to a state describing three spin-\(\frac{1}{2}\) particles or three qubits (a qubit, or quantum bit, is the quantum version of the classical bit and corresponds to a spin-\(\frac{1}{2}\) particle). Two pure states belonging to a generic composite system \(H_2 \otimes \cdots \otimes H_2\), i.e. \(N\) parties each having a \(d\)-dimensional Hilbert space, are equivalent as far as their entanglement properties go when they can be transformed one into another by local unitary transformations. This argument gives a lower bound for the entanglement parameters, a generic state \(|\phi\rangle \in H_2^\otimes \cdots \otimes H_2\) depends on. Since the number of real parameters for describing it is \(2^{N+1}\), and the action of an element of the group of local unitary transformations \(U(2)^\otimes \cdots \otimes U(2)^\otimes\) is equivalent to the action of \(U(1) \times SU(2)^\otimes \cdots \otimes SU(2)^\otimes\), which depends on \(3N + 1\) real parameters, the number of entanglement parameters is bounded by \(2^{N+1} - (3N + 1)\). For our case this counting of entanglement parameters gives six, since we have \(N = 3\), and it can be proved that this is indeed the number of nonlocal parameters describing a state in \(H_2 \otimes H_2 \otimes H_2\) [17].

The above arguments imply that six independent quantities invariant under the action of the group of local unitary transformations will be enough, up to some discrete symmetry, to describe the entanglement properties of any three-qubit pure state. Given a generic state \(|\phi\rangle \in H_2^3\)

\[
|\phi\rangle = \sum_{i,j,k} t_{ijk} |ijk\rangle \quad i, j, k = 1, 2, \tag{21}
\]

where \(|i\rangle, |j\rangle, |k\rangle\) are the elements of a basis in each subsystem, A, B and C, the application of three local unitary transformations \(U^A, U^B\) and \(U^C\) transforms the coefficients \(t_{ijk}\) into

\[
t'_{ijk} = \sum \epsilon_{\alpha\beta\gamma} t_{ijk} \epsilon_{i\alpha j\beta} \epsilon_{j\beta k\gamma} t_{\alpha\beta\gamma}. \tag{22}
\]

From this expression it is not difficult to build polynomial combinations of the coefficient \(t_{ijk}\) which are invariant under local unitary transformations [17,18]. These quantities are good candidates for being an entanglement parameter. For example, one of these invariants is

\[
\sum t_{i_1 j_1 k_1} t^*_{i_2 j_2 k_2} t_{i_3 j_3 k_3} = tr(\rho_A^2), \tag{23}
\]

where \(\rho_A = tr_{BC}(|\phi\rangle\langle\phi|)\) is the density matrix describing the local quantum state of A (and the same happens for B and C). In [18] the six linearly independent polynomial invariants of minor degree were found (a trivial one is the norm) and a slightly modified version of these quantities was also proposed in [19]. In the rest of the paper we will not consider the norm, so the space of entanglement parameters of the normalized states belonging to \(H_2 \otimes H_2 \otimes H_2\) has dimension equal to five.

A particularly relevant polynomial invariant is the so-called tangle, \(\tau\), introduced in [20]. There is strong evidence that somehow it is a measure of the amount of “GHZ-ness” of a state [19–22]. It corresponds to the modulus of the hyperdeterminant of the hypermatrix given by the coefficients \(t_{ijk}\) [23], which from (21) corresponds to

\[
\tau(|\phi\rangle) = |H\det(t_{ijk})| = \left| \sum \epsilon_{i_1 i_2} \epsilon_{j_1 j_2} \epsilon_{k_1 k_2} \epsilon_{i_3 i_4} \epsilon_{j_3 j_4} \epsilon_{k_3 k_4} t_{i_1 j_1 k_1} t_{i_2 j_2 k_2} t_{i_3 j_3 k_3} t_{i_4 j_4 k_4} \right|, \tag{24}
\]

where \(\epsilon_{00} = \epsilon_{11} = 0\) and \(\epsilon_{01} = -\epsilon_{10} = 1\). This quantity can be shown to be symmetric under permutation of the indices \(i, j, k\).

Because of the interpretation of the tangle as a measure of the GHZ-like correlations, we will choose the position of the photon detectors, from the set of states (19), the ones that are associated to a maximum tangle. In the figure 1 it is shown the variation of the tangle with the position of the detectors. It is not difficult to see that the state of (19) with maximum tangle corresponds to the case \(k_1 \cdot k_2 = k_1 \cdot k_3 = -\frac{1}{\sqrt{2}}\), i.e. the most symmetric configuration, that we shall call “Mercedes-star” geometry.

The normalized state obtained from (19) for this geometry is

\[
|\psi\rangle = \frac{1}{\sqrt{6}} \left( |++-\rangle + |---\rangle + |++-\rangle + |--+\rangle + |--+\rangle + |+++\rangle \right). \tag{25}
\]
Note that the GHZ state has tangle equal to $\frac{1}{2}$, while the value of the tangle of (25) is lower,

$$\tau(|\psi\rangle) = \frac{1}{12}. \quad (26)$$

It is arguable that a “Mercedes-star” geometry was naturally expected to produce a maximum tangle state. Indeed, GHZ-like quantum correlations do not singularize any particular qubit.

Let us also mention that the state we have singled out has some nice properties from the point of view of group theory. It does correspond to the sum of two of the elements of the coupled basis resulting from the tensor product of three spin-$\frac{1}{2}$ particles, $\frac{1}{2} \otimes \frac{1}{2} \otimes \frac{1}{2}$, [24]

$$|\psi\rangle = \frac{1}{\sqrt{2}} \left( |\frac{3}{2}, +\rangle + |\frac{1}{2}, -\rangle \right). \quad (27)$$

where

$$|\frac{3}{2}, +\rangle = \frac{1}{\sqrt{3}} (|+++\rangle + |--+\rangle + |--+\rangle)$$

$$|\frac{1}{2}, -\rangle = \frac{1}{\sqrt{3}} (|---\rangle + |--+\rangle + |++-\rangle). \quad (28)$$

The quantum correlations of (25) will be now analyzed.

### IV. USEFUL DECOMPOSITIONS

In this section, the state (25) will be rewritten in some different forms that will help us to understand better its nonlocal properties. First, let us mention that for any generic three-qubit pure state and by performing change of local bases, any state can be written with the minimum number of coefficients $t_{ijk}$ of (21) [19,25]. A simple counting of parameters shows that this is in fact the expected number of zeros. This means that by a right choice of the local bases, any state can be written with the minimum number of coefficients $t_{ijk}$, i.e. we are left with all the non-local features of the state, having removed all the “superfluous” information due to local unitary transformations. For the case of the state (25) it is easy to prove [26] that it can be expressed as

$$|\psi\rangle = \frac{1}{2\sqrt{3}} (|001\rangle + |010\rangle + |100\rangle) + \frac{\sqrt{3}}{2} |111\rangle, \quad (29)$$

which is the minimum decomposition in terms of product states built from local bases (four of the coefficients $t_{ijk}$ are made equal to zero).

An alternative decomposition, that will prove to be fruitful for the rest of the paper, consists of writing the state as a sum of two product states. This decomposition is somewhat reminiscent of the form of the GHZ state, which is a sum of just two product states, and is only possible when the tangle is different from zero [19,21] as it happens for our state (see 26). The state then can be written as

$$|\psi\rangle = \frac{2}{3} \left( \left( \frac{1}{\sqrt{3}} \right) \otimes \left( \frac{1}{\sqrt{3}} \right) \otimes \left( \frac{1}{\sqrt{3}} \right) \right) + a(|000\rangle + |aaa\rangle), \quad (30)$$

where $|0\rangle \equiv \left( \begin{array}{c} 1 \\ 0 \end{array} \right)$ and $a \equiv \left( \begin{array}{c} \frac{\sqrt{3}}{2} \\ \frac{\sqrt{3}}{2} \end{array} \right)$. We omit the details for the explicit computation of this expression since they can be found in [19,21]. It is worth noticing that o-Ps decay is hereby identified to belonging to an interesting type of states already classified in quantum information theory [21].

The above decomposition allows for an alternative interpretation of the initial state as an equally weighted sum of two symmetric product states. Note that the Bloch vector, $\hat{n} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$, representing the first local spinor appearing in (30) is pointing to the $z$ axis, i.e. $\hat{n}_1 = (0, 0, 1)$, while the second is located in the $XZ$ plane with an angle of $120^\circ$ with the $z$ axis, i.e. $\hat{n}_2 = (\frac{\sqrt{3}}{2}, 0, -\frac{1}{2})$. By performing a new unitary transformation, (30) can be written as

$$|\psi\rangle = \frac{2}{3} \left( \left( c \right) \otimes \left( c \right) \otimes \left( c \right) + \left( s \right) \otimes \left( s \right) \otimes \left( s \right) \right), \quad (31)$$

where $c = \cos 15^\circ, s = \sin 15^\circ$. Now, the two Bloch vectors are in the $XZ$ plane, pointing to the $\theta = 30^\circ$ and $\theta = 150^\circ$ directions. The GHZ state corresponds to the particular case $c = 1$ and $s = 0$. 

6
The quantum correlations present in some three-qubit pure states show, as it was mentioned in the introduction, a much stronger disagreement with the predictions of a local-realistic model than any two-qubit entangled state. In fact, contrary to the case of the singlet state, no LR model is able to reproduce all the perfect correlations predicted for the maximally entangled state of three qubits [2]. The state (25) emerging from o-Ps decay is not a GHZ state, although it has been chosen the one with the maximum tangle in order to maximize GHZ-like correlations. In this section we will show how to use it for testing quantum mechanics against local-realistic models, and then we will compare its performance against existing tests for the maximally entangled states of two and three spin-$\frac{1}{2}$ particles.

We start reviewing some of the consequences derived from the arguments proposed in [1].

A. QM vs LR conflict

Given a generic quantum state of a composite system shared by $N$ parties, there should be an alternative LR theory which reproduces all its statistical predictions. In this LR model, a state denoted by $\lambda$ will be assigned to the system specifying all its elements of physical reality. In particular, the result of a measurement depending on a set of parameters $\{n\}$ performed locally by one of the parties, say A, will be specified by a function $a_\lambda(\{n\})$. The same will happen for each of the space-separated parties and, since there is no causal influence among them, the result measured on A can not modify the measurement on B. For example, if the measurement is of the Stern-Gerlach type, the parameters labeling the measurement are given by a normalized vector $\hat{n}$ and $a_\lambda(\hat{n}) \equiv a$ are the LR functions describing the outcome.

The LR model can be very general provided that some conditions must be satisfied. Consider a generic pure state belonging to $\mathcal{H}_2 \otimes \mathcal{H}_2 \otimes \mathcal{H}_2$ shared by three observers A, B and C, which are able to perform Stern-Gerlach measurements in any direction. Since the outcomes of a Stern-Gerlach measurement are only $\pm 1$, it is easy to check that for any pair of measurements on each subsystem, described by the LR functions $a$ and $a'$, $b$ and $b'$, $c$ and $c'$, and for all their possible values, it is always verified

$$a'bc + ab'c + abc' - a'b'c' = \pm 2. \quad (32)$$

It follows from this relation that

$$-2 \leq \langle a'bc + ab'c + abc' - a'b'c' \rangle \leq 2. \quad (33)$$

This constraint is known as Mermin inequality [27] and has to be satisfied by any LR model describing three space-separated systems.

Let us now take the GHZ state (2). It is quite simple to see that if the observables $a$ and $a'$ are equal to $\sigma_y$ and $\sigma_x$ (the same for parties B and C), the value of (33) is $-4$, so an experimental condition is found that allows to test quantum mechanics against local realism. Note that this is the maximal violation of inequality (33). Moreover, the GHZ state also satisfies that $a'bc = ab'c = abc = -a'b'c' = -1$ and no LR model is able to take into account this perfect correlation result because of (32) [2]. This is a new feature that does not appear for the case of a two maximally entangled state of two spin-$\frac{1}{2}$ particles. In this sense it is often said that a most dramatic contrast between QM and LR emerges for entanglement between three subsystems.

Let us go back to the state given by the ortho-positronium decay (25). Our aim is to design an experimental situation where a conflict between QM and LR appears, so we will look for the observables that give a maximal violation of (33). Such observables will extremize that expression. Using the decomposition (31), the expectation value of three local observables is

$$\langle abc \rangle = \langle \psi | \hat{n}_a \cdot \vec{\sigma} \otimes \hat{n}_b \cdot \vec{\sigma} \otimes \hat{n}_c \cdot \vec{\sigma} | \psi \rangle$$

$$= \frac{4}{9} \left( \prod_{i=a,b,c} (\hat{c} \cos \theta_i + \hat{s} \sin \theta_i \cos \phi_i) + \prod_{i=a,b,c} (\hat{c} \cos \theta_i + \hat{s} \sin \theta_i \cos \phi_i) \right) \sin \theta_i (c^2 e^{-i\phi_i} + s^2 e^{i\phi_i}) + \prod_{i=a,b,c} \sin \theta_i (c^2 e^{-i\phi_i} + s^2 e^{i\phi_i}) \right), \quad (34)$$
where \( \hat{c} \equiv c^2 - s^2 \) and \( \hat{s} \equiv 2sc \). Because of the symmetry of the state under permutation of parties, the Stern-Gerlach directions are taken satisfying \( \hat{n}_a = \hat{n}_b = \hat{n}_c = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta) \) and \( \hat{n}_{a'} = \hat{n}_{b'} = \hat{n}_{c'} = (\sin \theta' \cos \phi', \sin \theta' \sin \phi', \cos \theta') \). Substituting this expression in (33), we get the explicit function \( f(\theta, \phi, \theta', \phi') \) to be extremized. For the case of the GHZ state described above, the extreme values were obtained using two observables with \( \theta = \theta' = \frac{\pi}{2} \), i.e. in the \( XY \) plane. Since (31) is the GHZ-like decomposition of the initial state, we take \( \theta = \theta' = \frac{\pi}{2} \) and it is easy to check that in this case \( \frac{\partial f}{\partial \theta} \bigg|_{\theta=\theta'=\frac{\pi}{2}} = \frac{\partial f}{\partial \phi} \bigg|_{\theta=\theta'=\frac{\pi}{2}} = 0, \forall \phi, \phi' \). Maintaining the parallelism with the GHZ case, it can be seen that all the partial derivatives vanish when it is also imposed \( \phi = \frac{\pi}{2} \) and \( \phi' = 0 \). In our case the calculation of (33) gives \(-3\), so a conflict between local-realistic models and quantum mechanics again appears, and then the three-photon state coming from the ortho-positronium decay can be used, in principle, to test QM vs LR with the set of observables given by the normalized vectors

\[
\hat{n}_a = \hat{n}_b = \hat{n}_c = (0,1,0) \quad \hat{n}_{a'} = \hat{n}_{b'} = \hat{n}_{c'} = (1,0,0).
\]

There is an alternative set of angles \( \phi \) and \( \phi' \) that makes zero all the partial derivatives of \( f \): the combination of local observables (33) is equal to \( -3.046 \) for

\[
\phi' = \arctan \left(-\frac{\sqrt{17+27\sqrt{41}}}{10}\right) \approx 126^\circ \quad \phi = \frac{1}{2} \arctan \left(\frac{2\sqrt{17+27\sqrt{41}}}{25}\right) \approx 24^\circ.
\]

This second set of parameters will be seen to produce in the end a weaker dismissal of LR.

Our next step will be to carry over the comparison of this QM vs LR test against the existent ones for the maximally entangled states of three and two spin-\( \frac{1}{2} \) particles, i.e. the GHZ and singlet state. It is quite evident that the described test should be worse than the obtained for the GHZ state. It is less obvious how this new situation will compare with the singlet case.

**B. Comparison with the maximally entangled states of two and three spin-\( \frac{1}{2} \) particles**

We will now estimate the “strength” of the QM vs LR test proposed above, being this “strength” measured by the number of trials needed to rule out local-realism at a given confidence level, as Peres did in [28]. A reasoning analogous to the one given in [28] will be done here for the state (25) and the observables (35).

Imagine a local-realistic physicist who does not believe in quantum mechanics. He assigns prior subjective probabilities to the validity of LR and QM, \( p_r \) and \( p_q \), expressing his personal belief. Take for instance \( p_r = 100 \). His LR theory is not able to reproduce exactly all the QM statistical results of some quantum states. Consider the expectation value of some observable \( \mathcal{O} \) with two outcomes \( \pm 1 \) such that \( \langle \mathcal{O} \rangle = E_q \) is predicted for some quantum state, while LR gives \( \langle \mathcal{O} \rangle = E_r \neq E_q \). Since the value of the two possible outcomes are \( \pm 1 \), the probability of having \( \mathcal{O} = +1 \) is \( q = \frac{1+E_q}{2} \) for QM and \( r = \frac{1+E_r}{2} \) for LR. An experimental test of the observable \( \mathcal{O} \) now is performed \( n \) times yielding \( m \) times the result \( +1 \). The prior probabilities \( p_q \) and \( p_r \) are modified according to the Bayes theorem and their ratio has changed to

\[
\frac{p'_r}{p'_q} = \frac{p_r \, p(m|LR)}{p_q \, p(m|QM)},
\]

where

\[
p(m|LR) = \binom{n}{m} \, r^m \, (1-r)^{n-m},
\]

is the LR probability of having \( m \) times the outcome \( +1 \), and we have the same for \( p(m|QM) \), being \( r \) replaced by \( q \). Following Peres [28], the **confidence depressing factor** is defined

\[
D \equiv \frac{p(m|QM)}{p(m|LR)} = \left(\frac{q}{r}\right)^m \frac{1-q}{1-r} \left(\frac{1}{1-r}\right)^{n-m},
\]

which accounts for the change in the ratio of the probabilities of the two theories, i.e. it reflects how the LR belief changes with the experimental results. Like in a game, our aim is to destroy as fast as we can the LR faith of our friend by choosing an adequate experimental situation. It can be said, for example, that he will give up when, for
example, \( D = 10^4 \). Since the world is quantum, \( m = qn \), and the number of experimental tests needed to obtain\( D = 10^4 \) is equal to

\[
n_D(q, r) = \frac{4}{q \log_{10} \left( \frac{q}{2} \right) + (1 - q) \log_{10} \left( \frac{1 - q}{2} \right)} = \frac{4}{K(q, r)},
\]

being \( K(q, r) \) the information distance [29] between the QM and LR binomial distribution for the outcome +1. The more separate the two probability distributions are, measured in terms of the information distance, the fewer the number of experiments \( n_D \) is.

Let us come back to the three-party entangled state coming from the ortho-positronium decay (25) under the local measurements described by (35). As it has been shown above, a contradiction with any LR model appears for the combination of the observables given by the Mermin inequality. In our case quantum mechanics gives the following predictions

\[
\langle a'bc \rangle = \langle ab'c' \rangle = \langle abc' \rangle = \langle ab'c' \rangle = +1,
\]

and this implies that \( q_1 = \text{prob}(a'bc = +1) = \text{prob}(ab'c = +1) = \text{prob}(abc = +1) = \frac{1}{6} \) and \( q_2 = \text{prob}(a'bc = +1) = 1 \). This is the QM data that our LR friend has to reproduce as well as possible. Because of the symmetry of the state he will assign the same probability \( r_1 \) to the events \( a'bc = +1, ab'c = +1 \) and \( abc = +1 \) and \( r_2 \) to \( a'bc = +1 \). However, his model has to satisfy the constraint given by (33), so the best he can do is to saturate the bound and then

\[
3r_1 = r_2 \implies 0 \leq r_1 \leq \frac{1}{3}.
\]

Now, according to the probabilities \( r_1 \) and \( r_2 \) his LR model predicts, we choose the experimental test that minimizes (40), i.e. we consider the event \( a'bc = +1 \) (\( a'bc = +1 \) when \( n_D(q_1, r_1) < n_D(q_2, r_2) \) (\( n_D(q_1, r_1) > n_D(q_2, r_2) \)), and the experimental results will destroy his LR belief after \( n_D(q_1, r_1) (n_D(q_2, r_2)) \) trials. The best value our LR friend can assign to \( r_1 \) is the solution to

\[
n_D(q_1, r_1) = n_D(q_2, r_2),
\]

with the constraint (42), and this condition means that \( r_1 \approx 0.315 \) and \( n_D \approx 161 \) trials are needed to have a depressing factor equal to \( 10^4 \). Repeating the same calculation for the observables giving by (36), the number of trials slightly increases, \( n_D \approx 166 \), despite of the fact that the violation of the inequality is greater than the obtained for (35).

In ref. [28] the same reasoning was applied to the maximally entangled state of two and three spin-\( \frac{1}{2} \) particles, showing that \( n_D \approx 200 \) in the first case, and \( n_D \approx 32 \) for the latter (see table I). Our result then implies that the three-photon entangled state produced in the ortho-positronium decay has, in some sense, more quantum correlations than any entangled state of two spin-\( \frac{1}{2} \) particles.

C. Generalization of the results

It is easy to generalize some of the results obtained for the entangled state resulting from the o-Ps decay. As it has been mentioned, this state can be understood as an equally weighted sum of two symmetric product states, since it can be written as (31). The Bloch vectors of the two local states appearing in this decomposition form an angle of \( 120^\circ \). It is clear that the conclusions seen above depend on the angle between these vectors, i.e. with their degree of non-orthogonality. The family of states to be analyzed can be parametrized in the following way

\[
|\psi(\delta)\rangle = \alpha_\delta \left( \left( \begin{array}{c} c_\delta \\ s_\delta \end{array} \right) \otimes \left( \begin{array}{c} c_\delta \\ s_\delta \end{array} \right) \otimes \left( \begin{array}{c} c_\delta \\ s_\delta \end{array} \right) \right),
\]

where \( \delta \) is the angle between the two local Bloch vectors, \( c_\delta \equiv \cos \left( \frac{\pi - \delta}{4} \right) \) and \( s_\delta \equiv \sin \left( \frac{\pi - \delta}{4} \right) \) and \( \alpha_\delta \) is a positive number given by the normalization of the state. An alternative parametrization of this family is, using (29) and defining \( \delta' \equiv \frac{\delta}{4} \),

\[
|\psi(\delta)\rangle = 2^{\alpha_\delta} \left( \sin^2 \delta' \cos \delta' (|001\rangle + |010\rangle + |100\rangle) + \cos^3 \delta'|111\rangle \right).
\]
symmetrization in the $K^0$ tagging would be carried by other quantum numbers, as e.g. charge. It is, on the other hand, peculiar to note that geometric tagging [10]. It is, thus, reasonable to look for pure GHZ states in decays to distinct particles, so that inducing a loss of tangle. The quantum optics realization of the GHZ state does avoid symmetrization through a symmetrized due to the absence of photon tagging to our state Indeed, the natural GHZ combination close to a product state [25], and thus, no violation of the Mermin inequality can be observed.

VI. CONCLUDING REMARKS

In this work we have analyzed the three-particle quantum correlations of a physical system given by the decay of the ortho-positronium into a three-photon pure state. After obtaining the state describing the polarization of the three photons (25), some of the recent techniques developed for the study of three-party entanglement have been applied. The particular case where the three photons emerge in a symmetric, Mercedes-star-like configuration, corresponds to the state with the maximum tangle. We have shown that this state allows a priori for a QM vs LR test which is stronger than any of the existing ones that use the singlet state. In this sense, ortho-positronium decays into a state which carries stronger quantum correlations than any entangled state of two spin-$\frac{1}{2}$ particles.

Bose symmetrization has played a somewhat negative role in reducing the amount GHZ-ness of the o-Ps decay state. Indeed, the natural GHZ combination $|+++\rangle+|--\rangle$ emerging from the computation of Feynmann diagrams has been symmetrized due to the absence of photon tagging to our state $|+++\rangle+|--\rangle+|---\rangle+|--+\rangle+|-+\rangle+|--\rangle$, inducing a loss of tangle. The quantum optics realization of the GHZ state does avoid symmetrization through a geometric tagging [10]. It is, thus, reasonable to look for pure GHZ states in decays to distinct particles, so that tagging would be carried by other quantum numbers, as e.g. charge. It is, on the other hand, peculiar to note that symmetrization in the $K^0\bar{K}^0$ system is responsible for its entanglement $\langle |+-\rangle + |--\rangle \rangle$ [13].

Finally, let us briefly discuss the experimental requirements needed for testing quantum mechanics as it has been described in this paper. In order to do this, the circular polarizations of the three photons resulting from an ortho-positronium decay have to be measured. The positions of the three detectors are given by the “Mercedes-star” geometry and their clicks have to detect the coincidence of the three photons. The energy of these photons is of the order of 1 Mev. Polarization analyzers with a good efficiency would allow us to acquire statistical data showing quantum correlations which would violate the Mermin inequality discussed above. Unfortunately, as far as we know, no such analyzers exist for this range of energies. A possible way-out might be to use Compton scattering to measure the photon polarizations [30]. However, Compton effect just gives a statistical pattern depending on the photon and electron polarizations which is not a direct measurement of the polarizations. Further work is needed to modify our analysis of QM vs LR to accommodate for such indirect measurements.

ACKNOWLEDGMENTS

We acknowledge J. Bernabeu for suggesting positronium as a source of three entangled particles and reading carefully the paper. We also thank A. Czarnecki, D. W. Gidley, M. A. Skalsey and V. L. Telegdi for comments about the measurement of the photon polarizations in the ortho-positronium decay. We acknowledge financial support by CICYT project AEN 98-0431, CIRIT project 1998SGR-00026 and CEC project IST-1999-11053, A. A. by a grant from MEC (AP98). Financial support from the ESF is also acknowledged. This work was concluded during the 2000 session of the Benasque Center for Science, Spain.

J. S. Bell, Physics 1 (1964), 195.

FIG. 1. Variation of the tangle with the position of the photon detectors, that are represented by two angles (the third one has to sum up to 360°). We have taken $\tau = 0$ when the position of the detectors, i.e. the photon trajectories, are incompatible with momentum conservation.

FIG. 2. Violation of the Mermin inequality (33) with the angle $\delta$ for the family of states (44). We have subtracted 2 to the combination of the expected values of (33), so a positive value means that a conflict between QM and LR appears.

FIG. 3. Number of trials needed to rule out local realism as a function of the angle $\delta$ for the family of states (44). Values greater than two hundred are not shown since in these cases there always exists a two-qubit entangled state which gives the same result, i.e. it has the same “strength” for ruling out local realism.
