Abstract

Three-particle correlations have been measured for identified π− from central 158 A GeV Pb+Pb collisions by the WA98 experiment at CERN. A substantial contribution of the genuine three-body correlation has been found as expected for a mainly chaotic and symmetric source.

In nuclear and particle physics, the study of Bose-Einstein correlations between identical particles is widely used. It is an essential tool to obtain information on the size and time evolution of expanding systems created in heavy ion collisions [1]. In particular, two-particle Bose-Einstein interferometry has been used for a sophisticated analysis of the dynamical evolution of the freeze out volume via selection on the transverse momentum and rapidity of the correlated particles.

Three-particle interferometry measurements can provide additional information on the space-time emission which is not accessible by two-particle interferometry[2, 3, 4, 5]. In particular, if the emission is fully chaotic, the three-particle interference study gives access to the phase of the source function’s Fourier transform, which is affected by the emission asymmetry. These asymmetries may be induced by source geometry, flow or resonance decays. If the source is not completely chaotic, as is likely to be the case, the interpretation is more difficult. Nevertheless, a comparison of the three-particle to the two-particle result allows to extract the relative strength of the true three-body correlation and can in principle remove obscuring effects, such as background from misidentified tracks or long-lived decay products, and therefore provide information more directly about the degree of coherence of the emission source[4]. In this letter we present first results from three-particle interferometry in central 208Pb+208Pb collisions at the CERN SPS.

The fixed target experiment WA98 [6] combined large acceptance photon detectors with a two arm charged particle tracking spectrometer. The incident 158 A GeV Pb beam impinged on a Pb target near the entrance of a large dipole magnet. The results presented here have been obtained from an analysis of the 1995 data set. These data were taken with the most central triggers corresponding to about 10% of the minimum bias cross section of 6190 mb. The π− measurements were obtained with data from the negative particle tracking arm of the spectrometer. This tracking arm consisted of six multistep avalanche chambers with optical
A time of flight detector with a time resolution better than 120 ps allowed for particle identification. The rapidity acceptance ranged from \( y = 2.1 \) to 3.1 with an average at 2.7, close to mid-rapidity which was 2.9. The momentum resolution of the spectrometer was \( \Delta p/p = 0.005 \) at \( p = 1.5 \) GeV/c. Severe track quality cuts were applied, resulting in a final sample of \( 4.2 \times 10^6 \) \( \pi^- \), providing \( 7.2 \times 10^6 \) pairs and \( 8.2 \times 10^6 \) triplets. The \( \pi^- \pi^- \) correlation analysis has been reported elsewhere [8].

The most common use of hadron interferometry concerns the study of pairs of identical particles. The two-particle correlation function can be defined as

\[
C_2(p_1, p_2) = \frac{d^2N(p_1, p_2)/dp_1dp_2}{dN(p_1)/dp_1 \cdot dN(p_2)/dp_2}
\]

where \( p_1 \) and \( p_2 \) are the 3–momenta of the correlated particles. The product of single particle distributions in the denominator is usually obtained experimentally by a mixed event technique whereas the pair distribution in the numerator is constructed from all pair combinations of identical particles found in each event. \( C_2 \) is normalized to unity far away from the interference region. In the plane wave approximation for chaotic sources of identical particles

\[
C_2 = 1 \pm |F_{12}|^2 \tag{1}
\]

with the + (−) sign for bosons (fermions). \( F_{12} \) is the Fourier transform of the space-time source function \( S(x, k_{12}) \)

\[
|F_{12}|^2 = \frac{\int d^4x \, S(x, k_{12}) \, \exp[iq_{12}x]|^2}{\int d^4x \, |S(x, k_{12})|^2} \tag{2}
\]

with \( q_{12} = p_1 - p_2 \), the 4–momentum difference of the two particles, and \( k_{12} = (p_1 + p_2)/2 \).

Typically \( \pi \pi \) correlation data are fit with a Gaussian form for \(|F_{12}|^2\)

\[
C_2 = 1 + \lambda \exp[-Q_{12}^2 R^2] \tag{3}
\]

or an exponential form

\[
C_2 = 1 + \lambda \exp[-2Q_{12} R] \tag{4}
\]

where the parameter \( \lambda \) is inserted to take into account the possibility that the source may not be fully chaotic and also that any wrongly reconstructed tracks, or tracks coming from decays of long-lived resonances, will dilute the correlations in the data.

The measurement of \( C_2 \) gives access to the radius \( R \) of the source, but not to the phase \( \phi_{12} \) contained in \( F_{12} = |F_{12}| \exp[i\phi_{12}] \) since \( C_2 \) is only a function of the square of the Fourier transform of the source distribution \( S \). By contrast, the three-boson interference produced by a fully chaotic source is sensitive to the phase information of the Fourier transform of the source emission function. Indeed, for a chaotic source the three-body correlation function \( C_3 \), which is

\[
C_3(p_1, p_2, p_3) = \frac{d^3N(p_1, p_2, p_3)/dp_1dp_2dp_3}{dN(p_1)/dp_1 \cdot dN(p_2)/dp_2 \cdot dN(p_3)/dp_3}
\]
can be written [2, 3, 4, 5] as

$$C_3 = 1 + |F_{12}|^2 + |F_{23}|^2 + |F_{31}|^2 + 2 \cdot \text{Re}\{F_{12} \cdot F_{23} \cdot F_{31}\}$$  \hspace{1cm} (5)

where $F_{ij}$ is the Fourier transform for the pair $ij$ contained in the triplet $123$. The genuine three-body correlation in $C_3$ is the term $2 \cdot \text{Re}\{F_{12} \cdot F_{23} \cdot F_{31}\}$.

With $F_{ij} \equiv |F_{ij}| \exp[i\phi_{ij}]$ and $W \equiv \cos(\phi_{12} + \phi_{23} + \phi_{31})$ one may rewrite

$$2 \cdot \text{Re}\{F_{12} \cdot F_{23} \cdot F_{31}\} = 2 \cdot |F_{12}| \cdot |F_{23}| \cdot |F_{31}| \cdot W.$$  \hspace{1cm} (6)

Having determined $|F_{ij}|$ from the pair correlation function $C_2$, the measurement of $C_3$ gives direct access to $W$, the cosine of the sum of the three phases of the Fourier transforms, and hence provides complementary information on the shape of the source. Indeed, $W$ is related to the odd space-time moments of the source which generate the phases $\phi_{ij}$ [4]. For example, if the source is fully chaotic and symmetric, $F_{ij}$ are real, $\phi_{12} = \phi_{23} = \phi_{31} = 0$, and $W$ is equal to 1. $C_3$ is then fully determined by $C_2$, and the genuine three-particle correlation is maximum. If the source is not fully chaotic, more complicated expressions should be used, mixing the effects of fully chaotic and coherent sources [4]. Nevertheless, Eq. 6 is valid in general with $W$ interpreted as a factor expressing the relative strength of the true three-body correlation compared to that expected for a fully symmetric chaotic source. Consequently, measuring $W$ values less than 1 does not allow to differentiate between asymmetries or coherence in the source.

Assuming a Gaussian form of the source function, which for two bosons leads to a correlation function described by Eq. 3, one obtains

$$C_3 = 1 + \lambda \sum_{ij=12,23,31} \exp[-Q_{ij}^2 R^2] + 2\lambda^{3/2} \exp[-Q_3^2 R^2/2] \cdot W$$  \hspace{1cm} (7)

with $Q_3 \equiv Q_{12}^2 + Q_{23}^2 + Q_{31}^2$. If the exponential form of the Fourier transform is assumed instead (Eq. 4), one obtains

$$C_3 = 1 + \lambda \sum_{ij=12,23,31} \exp[-2Q_{ij} R] + 2\lambda^{3/2} \exp[-(Q_{12} + Q_{23} + Q_{31})R] \cdot W$$  \hspace{1cm} (8)

Inserting the values of $\lambda$ and $R$ obtained from the two-particle analysis into Eqs. 7 or 8, one can extract the three-particle strength information $W$.

The one-dimensional correlation function $C_2$, analyzed in terms of $Q_{12}$, is shown in Fig. 1. The two-track resolution of the spectrometer (2 cm) is dealt with by application of a proximity cut to each track pair. The data are corrected for the Coulomb and strong final state interactions in an iterative way [10], taking into account the source size obtained in the fit. The Gamow correction was abandoned as we found that it overcorrects the data for $Q_{12}$ in the range of 0.1 to 0.3 GeV/c. The effect of the experimental resolution, which is estimated by a full Monte-Carlo, can be approximated in the interference region by a Gaussian of constant $\sigma$ of 7 MeV/c both for $Q_{12}$ and $Q_3$. It is taken into account by replacing the function $C_2(Q_{12})$ used to fit the non-corrected data by

$$C_2^{rc}(Q_{12}) = \int r(Q_{12}, Q_{12}^\prime) C_2(Q_{12}^\prime) dQ_{12}^\prime,$$
which is the convolution of $C_2(Q_{12})$ with the resolution function $r(Q_{12}, Q'_{12})$ of the spectrometer. For display purposes, Fig. 1 is obtained by multiplying each data point by $C^{rc}_2(Q_{12})/C_2(Q_{12})$. Fitting the corrected data with $C_2$ gives the same results as fitting the non-corrected data with $C^{rc}_2$. The correlation function $C_2$ is seen to be non-Gaussian. Instead, it is better represented by an exponential form[8]. For the $C_3$ analysis, an accurate description of the shape of $C_2$ is essential since the estimate of the $W$ factor extracted from $C_3$ depends on it. The exponential fit (Eq. 4) yielding $R = 7.29 \pm 0.11$ fm and $\lambda = 0.753 \pm 0.013$ is shown in Fig. 1.

Fig. 2 shows the three-pion correlation as a function of $Q_3$, after correction for resolution. A very strong $\pi^-\pi^-\pi^-$ correlation is observed, which is robust under all tracking criteria. The result shown is obtained for the same sample and the same cuts applied on the three pair combinations contained in each triplet as used for the two-pion interference analysis. For the $C_3$ result, the Coulomb correction applied to a particular triplet is the product of the Coulomb corrections used for the three pair combinations contained in that triplet. The resolution is taken into account using the same procedure as in the two-pion analysis. The resolution has a tiny effect compared to the Coulomb correction and it has been checked that the results are not affected by the order in which these corrections are applied to the data. The dashed line is a fit to a double exponential function

$$C_3 = 1 + \lambda_1 \exp[-2Q_3R_1] + \lambda_2 \exp[-2Q_3R_2]$$

with fitted parameters $R_1 = 5.01 \pm 0.38$ fm, $\lambda_1 = 2.79 \pm 0.32$, $R_2 = 1.72 \pm 0.12$ fm, $\lambda_2 = 0.343 \pm 0.072$ and $\chi^2/d.o.f. = 0.88$. The three-pion correlation data cannot be well fitted by a Gaussian or a single exponential as a function of $Q_3$. Such non-Gaussian behaviour has been predicted by a final-state rescattering model [11].

In Fig. 2, the three-pion correlation data are compared to an estimate using Eq. 8 with $W = 1$ (upper line) and $W = 0$ (lower line). This estimate is made using triplets from mixed events with the $\lambda$ and $R$ parameters extracted from the two-pion interferometry analysis. Although the calculated contribution to $C_3$ from the genuine three-pion correlation is rather small and becomes insignificant for $Q_3 > 60 – 80$ MeV/c, the experimental results clearly indicate a $W$ factor which lies between 0 and 1.

As proposed in Refs. [4, 12], a method to extract the experimental value of $W$ as a function of $Q_3$ is to invert Eqs. 5 and 6 and rewrite $|F_{ij}|$ in terms of $C_2$ using Eq. 1 to obtain

$$W = \frac{|C_3(Q_3) - 1| - |C_2(Q_{12}) - 1| - |C_2(Q_{23}) - 1| - |C_2(Q_{31}) - 1|}{2 \cdot \sqrt{|C_2(Q_{12}) - 1||C_2(Q_{23}) - 1||C_2(Q_{31}) - 1|}}$$

In this method, the analysis must be performed in two steps. First, the $\lambda$ and $R$ parameters are determined both for the two-pion and three-pion correlations with a fit to the data of Eqs. 4 and 9 as previously explained. Then the data are analyzed again, and, for each triplet found, characterized by the value $Q_3$, $W$ is determined using Eqs. 4, 9, and 10 with the values $Q_{12}$, $Q_{23}$, and $Q_{31}$ corresponding to the three pair combinations contained in the triplet. For each bin in $Q_3$ containing $N$ triplets, the statistical error on the mean value $(W)$ is $\sigma/\sqrt{N}$, where $\sigma^2$ is the variance of the $W$ distribution in this particular bin. The estimate of systematic errors is done by varying the different analysis cuts in the two and three-pion interference studies. It includes in particular the cuts used to identify the pions with the time of flight system. The systematic error on the Coulomb correction due to the error on the
determination of the R parameter in the two-pion fit, as well as a possible 10% systematic error on the evaluation of the $Q_{12}$ and $Q_3$ resolution are also taken into account. The effects on $W$ of the statistical errors in the determination of $C_2$ and $C_3$ are treated as systematic errors by changing $C_2$ and $C_3$ respectively by $\pm \sigma C_2$ and $\pm \sigma C_3$. All of these variations are then added in quadrature.

Fig. 3 shows the $W$ values obtained for five bins of 10 MeV/c in $Q_3$. The error bars are the sum of statistical and systematic errors. The statistical errors (not shown separately in Fig. 3) are nearly negligible. The slight $Q_3$ dependence observed is not significant in view of the errors. The genuine three-body correlation is substantial with a weighted mean $\langle W \rangle = 0.606 \pm 0.005 \pm 0.179$ for $Q_3 < 60$ MeV/c. ¹ This result should be compared to the lower $\pi^+\pi^+\pi^+$ result of $\langle W \rangle = 0.20 \pm 0.02 \pm 0.19$ observed by the NA44 collaboration [12] in S+Pb minimum bias collisions at 200 GeV per nucleon.

In conclusion, we have studied the $\pi^-\pi^-\pi^-$ interference of pions produced in central Pb+Pb collisions at 158 GeV per nucleon. Although its contribution is small, the genuine three-pion correlation, the portion of the correlation not trivially due to the two-pion interference, has been extracted and found to be substantial. The genuine three-pion correlation is greater than reported for S+Pb minimum bias collisions [12], but not as large as expected for a fully chaotic and symmetric source.

We would like to thank the CERN-SPS accelerator crew for providing an excellent Pb beam. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR, the Dutch Stichting FOM, the Swiss National Fund, the Humboldt Foundation, the Stiftung für deutsch-polnische Zusammenarbeit, the Department of Atomic Energy, the Department of Science and Technology and the University Grants Commission of the Government of India, the Indo-FRG Exchange Programme, the PPE division of CERN, the INTAS under contract INTAS-97-0158, the Polish KBN under the grant 2P03B16815, the Grant-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science, Sports and Culture, JSPS Research Fellowships for Young Scientists, the University of Tsukuba Special Research Projects, and ORISE. ORNL is managed by UT-Battelle, LLC, for the U.S. Department of Energy under contract DE-AC05-00OR22725.

References

¹The weighted systematic error is obtained by calculating the weighted average over the five $Q_3$ bins separately for each kind of systematic error. These errors are then added in quadrature. On the contrary, adding quadratically the systematic errors of the five $Q_3$ bins as done for weighted statistical errors, or as done in [12], would give $\pm 0.097$ instead of $\pm 0.179$ for the systematic uncertainty.
