ABSTRACT

Using N-body numerical simulations, we examine possible mechanisms for the origin of the intracluster starlight features recently discovered in the Coma cluster of galaxies. We show that tidal interactions of a “normal” elliptical galaxy with a symmetrically distributed dark matter potential do not produce the observed intracluster starlight features. A head-on collision of two normal ellipticals does, however, explain the origin of the intracluster features with surface brightness about 26 mag/arcsec$^2$). Another possible explanation for the intracluster starlight features is galactic tidal interactions with massive intracluster substructures. The presence of substructures in Coma with a density of $\sim 0.1$ times the density in the center of the galaxy, and with a total mass about three orders of magnitude larger than the mass of a normal elliptical galaxy, would account for the observations.

Subject headings: GALAXIES: clusters: individual (Coma) — galaxies: interactions — galaxies: kinematics and dynamics — galaxies: evolution — intergalactic medium — methods: numerical

1. INTRODUCTION

Gregg & West (1998) have recently reported the discovery of intracluster starlight features in the Coma cluster of galaxies. The features are revealed in R-band images of the Coma cluster,
and are also seen in the B, V and I bands, confirming their existence. The plume-like features are tens of kiloparsecs in width, and extend to radii of more than a hundred kiloparsecs. The mean R-band surface brightness of the plumes is low, about 26 mag/arcsec², but their absolute magnitude \( \approx -19.0 \) mag is comparable to the absolute R-band magnitude of a normal elliptical galaxy. Possible explanations of the origin of the plumes invoke the idea of the disruption of galaxies by galaxy-galaxy interactions (Dubinski et al 1996, Moore et al 1996), or the tidal stripping of galaxies by the global cluster gravitational field (Merritt 1984). However, the stellar plumes observed in the Coma cluster can not be produced so easily. Using N-body simulations, we have studied the possibility of forming stellar plumes with surface brightnesses 6–7 magnitudes fainter than the surface brightness in the centers of the normal elliptical galaxies similar to those observed in the Coma cluster. We have found that the tidal interaction of galaxies with the gravitational field of the cluster core cannot be responsible for the origin of intracluster starlight features in Coma. A head-on collision of two normal elliptical galaxies with a relative velocity less than the cluster velocity dispersion, or tidal interactions with intracluster density inhomogeneities might explain the origin of stellar plumes with the observed properties.

2. MODELS AND NUMERICAL METHOD

To model galaxy disruptions by the cluster core or galaxy-galaxy collisions, we use the parameters of the elliptical galaxy NGC 3377. The disruptions of the disk galaxies might also lead to the formation of stellar plumes. Nearby clusters of galaxies, however, are enriched with elliptical and lenticular galaxies (Dressler 1980). The elliptical galaxy NGC 3377 was chosen by Gregg & West (1998) in their comparison between normal galaxies and the properties of the Coma stellar plumes. NGC 3377 is well studied observationally. Kormendy et al (1998) published an accurate rotation curve of this galaxy, along with a composite surface brightness profile along its major axis. The rotation curve of NGC 3377 shows a steep kinematic gradient near the center of the galaxy, but it remains flat for radii \( r > 3'' \), with a circular velocity about 100 km/sec. This yields a total mass for NGC 3377 of about \( 3 \times 10^{10} M_\odot \), if the galactic radius is \( \sim 140'' \) or 15 kpc assuming a Hubble constant \( H = 50 \) kms\(^{-1}\)Mpc\(^{-1}\), as used in our further simulations.

Using the rotational curve near the center, the central density of NGC 3377 can be rather firmly evaluated to be \( 2.2 \times 10^{-21} \) g/cm\(^3\) within the central 3''. Approximately half of the mass can be associated with the central black hole, and we adopt in our simulations the value \( 10^{-21} \) g/cm\(^3\).

For the radial dependence of the galactic density, we use the Plummer model, and Hernquist’s (1990) density distributions with core radii of 0.8 kpc and 0.6 kpc respectively. We adopt an analytic King approximation to the isothermal sphere (Sarazin 1986) for the dark matter density distribution in the Coma cluster. Hughes (1998) re-examined mass estimates for the Coma cluster derived from X-ray spectral observations. At the 99% confidence level, he found that the mass of the Coma cluster within a radius of 1 Mpc is \( (6.2 \pm 0.9) \times 10^{14} M_\odot \). The dark matter core radius
for the adopted matter profile is about 270-370 kpc (Hughes 1998), which gives a central dark matter density of \((1.0 - 2.9) \times 10^{15} M_\odot / \text{Mpc}^3\). In our simulations, we adopt “extreme” disruptive parameters of the Coma cluster which have the values \(r_c = 270\) kpc, and \(\rho_0 = 3 \times 10^{15} M_\odot / \text{Mpc}^3\).

The simulations were performed with a TREE code using \(N=32768\) particles, a tolerance parameter equal to 0.75, and a softening length of 0.03125.

3. RESULTS AND DISCUSSION

We considered different possibilities for the formation of stellar plumes in clusters of galaxies, namely the tidal disruption of an elliptical galaxy by the cluster core, direct galactic collisions, and the interaction of an elliptical galaxy with hypothetical cluster substructures.

Collisions or tidal interactions often produce plumes of particles in numerical simulations. We need, however, a quantitative estimate of whether such plumes could be responsible for the observed stellar structures seen in Coma. To do this, we calculated the theoretical surface brightness in the plume assuming constant mass-to-luminosity ratios for the plume and the galaxy. The characteristic surface brightness in the central regions of elliptical galaxies in the V-band is about 20 mag/arcsec\(^2\) (Binney & Merrifield 1998), which for the R-band, gives a value of about 19.5 mag/arcsec\(^2\) (Frei & Gunn 1994). We assumed that our model galaxy has the same surface brightness in central regions before an interaction, and that tidal interactions do not change the stellar content of the plume. These assumptions allow us to estimate surface brightness of resulting features in our numerical simulation by comparing corresponding column densities of particles. The last assumption excludes from our consideration the possible role of star formation triggered in the plumes by tidal interactions. Although tidally induced star formation in the plumes is likely to take place for the collisions of gas rich disk galaxies, this is not the case for the stellar plumes observed in Coma. According to Gregg & West (1998), the colors in the plumes are consistent with those of evolved stellar populations observed in intermediate brightness normal elliptical galaxies. The photometric uncertainties, and uncertainties of the removal of superimposed objects leave, however, open the possibility of significant star formation in the plumes.

**Direct galactic collisions.** Figure 1 shows the result of a direct collision of two equal-mass Plummer spheres taken at time \(1.7 \times 10^8\) years after the beginning of the interaction. The initial separation of the galaxies and their initial relative velocity were taken to be 32 kpc and 408 km/sec. The collision forms a broad stellar plume connecting both galaxies, with the surface brightness in the plume about 26.5 mag/arcsec\(^2\) (Figure 2). The direct collisions of equal-mass galaxies might therefore constitute a possible explanation of the origin of the observed stellar plumes in Coma. The high velocity dispersion of about 1000 km/sec in Coma, however, makes this mechanism rather ineffective. Gregg & West (1998) argue that the galactic subgroups in Coma, with their relatively low internal velocity dispersions, will increase the effectiveness of the disruption of galaxies, and our simulations concur with this conclusion. The characteristic velocity
dispersion within groups, which are fairly uniformly distributed in space and which show no preference for rich clusters, is about 250 km/sec (Hickson 1997). This value is much smaller than the typical velocity dispersions in rich clusters of galaxies. If a cluster is not virialized, then strong local interactions can occur within in-falling subgroups of galaxies (Conselice & Gallaher 1998). Burns et al (1994) present convincing arguments that such infalling groups of galaxies do indeed exist. They found that the galactic group NGC 4839 has fallen into the Coma Cluster, passing through the cluster core about 2 Gyr ago. The NGC 4839 galactic group cannot be responsible, however, for the observed starlight features in Coma. All four stellar features are located within ~ 0.5 Mpc of the cluster center, and cannot survive for more than 1-2 Gyr (Gregg & West 1998), which is shorter than the epoch of passage of the NGC 4839 group through the central regions of Coma.

**Core tidal interactions.** The tidal interaction of galaxies with the gravitational potential of the cluster core is a likely explanation for the origin of stellar intrachuster structures in Coma. We simulated an extreme case of such an interaction with a galaxy plunging into the cluster core. In these simulations, the cluster core radius adopted was 270 kpc, and the core density equal to \(3 \times 10^{15} M_\odot / \text{Mpc}^3\) which are the extreme “disruptive” parameters of the mass distribution in Coma. The galaxy was placed 600 kpc away from the cluster center with zero initial relative velocity. Figure 3 shows surface density contour plots taken at time \(T = 3.36 \times 10^9\) years after the beginning of the simulations, when the galaxy made one oscillation in the cluster core. The surface brightness in the patchy plume is 32-34 mag/arcsec\(^2\), and apparently cannot explain the origin of the bright starlight features in Coma. This result is also illustrated by Figure 4, which shows the fraction of escaped particles as a function of time. A total of 10 % of the mass is stripped during the interaction time. This stripped mass cannot be regarded as the main source of intrachuster stellar material in Coma.

**Tidal disruption by the “local core”.** One more possibility exists for the formation of the bright intrachuster structures seen in Coma. The X-ray surface brightness measurements of Coma cluster reveal the regions of the enhanced X-ray emission with characteristic angular size less than the core radius of the cluster (Soltan & Fabricant 1990). The intrachuster stellar features in Coma may result from tidal interactions with small scale density fluctuations associated with the enhanced X-ray emission. Vikhlinin et al (1994) found indeed such mass concentrations in the core region of the Coma cluster. Both of the discovered density enhancements are centered at the positions of the brightest elliptical galaxies in the cluster: NGC 4874 and NGC 4889. Assuming that X-ray surface brightness enhancements result from the density enhancements of the underlying dark matter, Vikhlinin et al (1994) estimated the masses of inhomogeneities within 80 kpc to be about \(10^{13} M_\odot\). Remarkably, the most prominent plume-like structure, the LSB object 1 discovered by Gregg and West, is adjacent to NGC 4874. The core radius of the density enhancement centered at the position of NGC 4874 is about 100 kpc (Vikhlinin et al 1994) which gives the density of the “local core” about \(5 \times 10^{-25} \text{g/cm}^3\). This value is too low to disrupt noticeably a galaxy by tidal interaction.
The parameters of the density enhancement centered at the position of NGC 4889 are more favorable for the galactic disruption. This density enhancement has core radius about 24 kpc, and the central density about $8 \times 10^{-24} \text{ g/cm}^3$. We simulated an interaction of a galaxy with the NGC 4889 density enhancement. A galaxy was placed 200 kpc away from the density enhancement with the initial velocity 500 km/s. The galaxy was allowed then to collide non-centrally with the density enhancement with the impact parameter equal to 24 kpc. Figure 5 shows the result of such high-speed tidal interaction. Interaction with NGC 4889 density inhomogeneity forms a plume with the surface brightness only 29-30 mag/arcsec$^2$. This value is too low to account for the properties of the observed plumes. The density enhancements, however, increase an effective cross-section of the direct collision with the giant cD galaxies nested in their central regions. This is a likely scenario of the formation of the most luminous plume LSB no 1 adjusted to NGC 4884.

Stars in the plume structures which are induced in direct galactic collisions have higher velocity dispersion compared to the plumes produced in tidal interactions. The collisional plumes live therefore shorter than tidally induced structures. Our numerical simulations show that the density inhomogeneities tidally disrupt an elliptical galaxy if the central density of a “local core” is about 10 percent of the central galactic density. Such value can be achieved if an inhomogeneity has total mass about one thousand of a mass of a normal elliptical galaxy, and a core radius $\leq 15$ kpc. If such inhomogeneities of the intracluster matter do really exist, then the starlight features in clusters of galaxies give an opportunity to probe the cluster density fluctuations.

4. SUMMARY

Our results can be summarized as follows:

1. We found that the observed intracluster starlight structures in Coma cannot be produced by the tidal interaction of an elliptical galaxy with the gravitational potential of the cluster core.

2. The head-on collision of two normal ellipticals with relative velocities lower than the velocity dispersion of the Coma cluster might be a mechanism for the formation of the stellar plumes observed in Coma. The subgroups of galaxies within the Coma cluster have relatively low velocity dispersions, and therefore direct galactic collisions within the subgroups are currently the most plausible explanation for the origin of the stellar plumes.

3. The stellar plumes seen in Coma may result from the tidal interactions of galaxies with local inhomogeneities of the cluster density distribution. If the existence of such inhomogeneities is confirmed in future observations, then intracluster starlight features will provide an opportunity for studying their nature.
