Abstract. We investigate the development of electromagnetic cascades in ice using a GEANT Monte Carlo simulation. We examine the Cherenkov pulse that is generated by the charge excess that develops and propagates with the shower. This study is important for the RICE experiment at the South Pole, as well as any test beam experiment which seeks to measure coherent Cherenkov radiation from an electromagnetic shower.

I INTRODUCTION

Ultra high energy neutrinos can travel a long distance without scattering. By detecting the sources of these particles, we can probe the physics of the standard model (and beyond) at energies un-obtainable at current accelerators. An ultra high energy neutrino can interact via a charge current interaction, giving most of its energy to the secondary electron, which can then initiate an electromagnetic cascade or shower. Askaryan [1] predicted a negative charge imbalance in the cascade which gives rise to coherent Cherenkov radiation at radio frequencies. The predicted flux of ultra high energy neutrinos is small and model dependent [2–4]. An experiment to detect ultra high energy neutrinos using radio antennas requires a large volume because of the small flux. A dense, radio-transparent target is needed for the small shower size needed for coherence and small signal attenuation. Antarctic ice is suitable for this purpose. A detailed analysis of such an experiment was done [5] which concluded that a modest array of antennas can detect many events per year. The Radio Ice Cherenkov Experiment (RICE) at the South Pole [6] is a prototype designed to detect neutrinos with energy \( \geq \) PeV using this method. A reliable Monte Carlo simulation tool is needed to study the shower development, Cherenkov radiation, detector, and data acquisition.
system. One can also test the idea of coherent Cherenkov emission at accelerator facilities by dumping bunches of electrons or photons in a dense target like sand or salt or any other suitable medium [7]. Zas, Halzen and Stanev (ZHS) [8] developed a Monte Carlo simulation to study electromagnetic showers and Cherenkov emission in ice. Buniy and Ralston [9] have also developed a method to estimate the coherent Cherenkov signal by parametrizing the cascades.

We have developed a GEANT Monte Carlo simulation primarily to study the coherent Cherenkov emission in ice but it can easily be modified for other similar studies with different materials. GEANT [10] is a well known and widely used detector simulation package in particle physics. It allows access to all details of the simulation such as controls of various processes, definition of target and detector media, and a complete history of all events simulated. It can be used to simulate all dominant processes in the $10 \text{ keV} - 10 \text{ TeV}$ energy range. Cross sections of electromagnetic processes are reproduced in GEANT within a few percent up to a hundred GeV. We use GEANT to simulate electromagnetic cascades inside materials from which we extract track information. We take this track information and determine the resulting radio pulse using standard electrodynamics calculations. We also calculate other shower parameters using the track and energy information from GEANT.

II SHOWER DESCRIPTION

When a high energy electron ($e^-$) or photon ($\gamma$) hits a material target, an electromagnetic cascade is created inside the material. Bremsstrahlung and pair production are the dominant high energy processes at the beginning of the shower development. Due to bremsstrahlung, an $e^-$ loses $1/e$ of its energy on average over a distance $X_0$, the radiation length. The secondary $\gamma$ can then produce an $e^+ e^-$ pair. The number of particles thus grows exponentially. $e^-$ and $e^+$ lose energy due to ionization as they travel inside the material. After reaching a critical energy ($E_c$), when the energy loss due to bremsstrahlung is equal the energy loss due to ionization, $e^-$, $e^+$ lose their energy mostly due to ionization and the cascade eventually stops. A rough estimate of the critical energy is $E_c \approx 605/Z \text{ MeV}$ which can be obtained by equating the radiation and the ionization loss formulae. $Z$ is the atomic number of the medium.

All models of an electromagnetic cascade, including a simplified model developed by Heitler [11], and a more realistic model developed by Carlson and Oppenheimer [12], show similar basic features which include linear scaling of the track lengths and logarithmic scaling of the maximum position with primary energy.

The cascade is concentrated near an axis along the direction of the primary. Multiple Coulomb scattering is responsible for the transverse spread of the cascade. A quantity called Moliere radius ($R_M$) is determined by the average
angular deflection per radiation length at the critical energy \( (E_c) \) and is used to estimate the transverse spread. One can also look at the fraction of energy that escapes transverse to the shower axis \([13,14]\) to get a good estimate of \( R_M \). About 90\% of the primary energy is contained inside a tube of radius \( R_M \) along the shower axis. A relationship between the Molière radius, the critical energy and the radiation length is \( R_M = X_0 E_s / E_c \) where \( E_s \approx 21.2 \, MeV \) is the scale energy.

Low energy processes like Compton, Moller and Bhabha scatterings and positron annihilation build up a net charge (more \( e^- \) than \( e^+ \)) in the cascade, as atomic electrons in the target medium are swept up into the forward moving shower.

### III ELECTROMAGNETIC PULSE

High energy \( e^- \) and \( e^+ \) in the cascade can travel faster than the speed of light in the medium and give rise to Cherenkov radiation. The electric field due to a single charge moving uniformly from position \( \vec{r}_1 \) to \( \vec{r}_2 = \vec{r}_1 + \vec{v} \delta t \) in the Fraunhoffer limit, is given by

\[
R \vec{E}(\omega) = \mu_r \frac{e \omega R}{\sqrt{2\pi} c^2} e^{i \omega (t_1 - n \beta \vec{r}_1)} \vec{v}_T \frac{e^{i \omega \delta t (1 - \hat{n} \cdot \vec{\beta} n)} - 1}{1 - \hat{n} \cdot \vec{\beta} n} (1)
\]

where \( \mu_r \) is the relative permeability and \( n \) is the refractive index of the medium. The condition \( 1 - \hat{n} \cdot \vec{\beta} n = 0 \) defines the Cherenkov angle \( \theta_c \) as \( \cos \theta_c = 1 / n \beta \). At or very close to the Cherenkov angle or at low frequency, the equation (1) can be reduced to the form

\[
R \vec{E}(\omega) = \mu_r \frac{i \omega}{\sqrt{2\pi}} \frac{e^{i \omega R}}{c^2} e^{i \omega (t_1 - n \beta \vec{r}_1)} \vec{v}_T \delta t. (2)
\]

See Fig. 1 for a description of various quantities in equations (1, 2).

### IV MONTE CARLO RESULTS

Since on average, the electrons lose \( 1/e \) of their energy in each radiation length due to bremsstrahlung, one can fit an exponential to the energy loss data generated by the Monte Carlo and find a value for the radiation length \( (X_0) \). This will serve as an internal consistency check to ensure that we are tracking all the particles along with their energies. We generated 500 showers of 50 GeV electrons and recorded the energy loss due to bremsstrahlung. A fit to this gives a radiation length of \( 41.5 \pm 3.2 \, cm \). Given the molecular composition, GEANT also calculates the medium’s radiation length. For ice it is \( 38.8 \, cm \), which is in agreement with the value we calculated.

To calculate the Moliere radius ($R_M$) we construct an imaginary cylinder centered on the shower axis (up to the physical length of the shower). We add the energy ($U$), of all the tracks that leave the cylinder without re-entering. By varying the radius of the cylinder we arrive at $R_M$ which is the radius of the cylinder when the fraction $U/E$ is equal to 0.1, $E$ being the initial energy of the cascade. We have checked $R_M$ for lead, iron and ice (see table I). One can also calculate the critical energy ($E_c$) using two different formulae quoted earlier.

Shower depth ($t$) is measured in units of radiation length ($X_0$) as $t = x / X_0$. We have simulated 30 GeV electron-induced cascades in iron. The longitudinal profile was obtained by adding the number of particles with total energy greater than 1.5 MeV crossing planes at every half radiation length perpendicular to the shower axis as shown in Fig. 2a. The number of particles agrees reasonably with EGS4 simulation of the same shower [15]. The Greisen-Rossi distribution for total number of particles (electrons and positrons) is shown by the dashed line. A least squares fit to the GEANT data with Greisen-Rossi distribution gives about 90% confidence level.

We used the same method to study the longitudinal profile of showers in ice. Simulation shows the correct scaling behavior of the number of particles with the initial energy of the shower. The position of the shower maximum also

FIGURE 1. Set-up to calculate electromagnetic pulse from a single track.
shows the correct logarithmic scaling with the initial energy. The charge excess \(\Delta Q\) is defined as \(\Delta Q = \frac{N(e) - N(p)}{N(e) + N(p)}\) where \(N(e)\) and \(N(p)\) are the number of electrons and positrons respectively as functions of shower depth. According to our simulations, the net charge imbalance is 15% – 18% at the shower max. Note that there is no direct experimental data on this.

A comparison of 100 GeV shower (averaged over 20 showers) with 611 KeV threshold from GEANT to the same from ZHS Monte Carlo (Fig. 2b) shows about a 25% – 35% discrepancy for the total number of particles at the shower max. The discrepancy between the two simulations remains the same at higher energies.

In Fig. 3, we show the charge excess in a 500 GeV shower from GEANT with kinetic energy threshold 1.5 MeV. This is an average of 20 showers and the charge excess is broken down to different energy bins. It shows that most of the contributions to charge excess come from the energy range 1.5 to 30 MeV. The Cherenkov pulse from a cascade is proportional to the total track length (energy deposition) of the cascade. Our results show the correct scaling behavior of the track lengths with the initial energy \(E_o\). If we consider all processes to be elastic except ionization, then an upper bound for the total track length is \(L = E_o/\langle \frac{dE}{dx}\rangle_{ion}\) where \(\langle \frac{dE}{dx}\rangle_{ion}\) is the average ionization energy loss per unit length. To determine \(\langle \frac{dE}{dx}\rangle\) we generated 500 of 1 GeV tracks and

**FIGURE 2.** (a) The longitudinal profile of a 30 GeV cascade in iron using GEANT (average of 30 showers) and comparison with the same produced by EGS4 (from particle data book) and by ZHS Monte Carlos. The error bars correspond to standard error. (b) Comparisons between the profiles of a 100 GeV cascade (averaged over 20 showers each) from GEANT and from ZHS Monte Carlos. The total energy threshold is 0.611 MeV in both cases.
kept a record of the rate at which energy was lost due to ionization. Fig. 4a shows the average \( \left( \frac{dE}{dx} \right) \) for the 500 tracks. It can be seen that the average value matches theoretical Bethe-Bloch result reasonably well. The average ionization loss in the relativistic rise region is approximately 1.9 MeV/cm.

V PULSE CALCULATION

To calculate the electric pulse from the cascade, we added up the contributions (1) from all charged tracks. There are two assumptions we made to evaluate pulse (1) and (2) from GEANT track information. First, we assume an azimuthal symmetry about the shower axis, which allows us to evaluate pulse equations in 2-dimensions. This is a good approximation as long as we have many tracks in the shower. A typical 500 GeV shower has thousands of tracks and the number goes up as we increase the energy. We checked this approximation on a shower-by-shower basis and did not find any noticeable difference between the pulses evaluated in the \( x-z \) plane and in the \( y-z \) plane (\( z \) - is the shower axis). Second, we evaluate the times \( t_1 \) and \( \delta t \) in (1) and (2) assuming that the particles travel at the speed of light. This is a good approximation if the frequency is not too high as can be seen from (1). In Fig. 4b, we calculate pulses\(^1\) from 1 TeV and 500 GeV showers at 1 GHz.

\(^1\) we use different normalization here for the field, which requiring that one multiply (1) and (2) by \( 2\sqrt{2\pi} \)

\[ \text{FIGURE 3. Excess charge plot for a 500 GeV cascade (averaged over 20 showers) in ice using GEANT. The excess charge is shown in energy bins (from bottom to top) 1.5-5 MeV (white), 5-30 MeV (light gray), 30-100 MeV (dark gray) and above 100 MeV (black).} \]
and 300 MHz frequencies. The pulse height at the Cherenkov peak ($\approx 55.8^\circ$) scales with the energy of the shower, and the Gaussian half width is inversely proportional to the frequency which is analogous to a slit diffraction pattern.

**VI CONCLUSION**

We find distinctive, coherent, Cherenkov radio frequency emission from simulated electromagnetic cascades in ice with energies in the 100 GeV to 1 TeV range. The multi-purpose, detector simulation package GEANT provides a suitable modelling of electromagnetic shower details for this purpose, with the flexibility to include hadronic cascades in future studies. This work also serves as an independent treatment of the problem, which has been studied previously [8]. The GEANT generated showers are qualitatively in agreement with those in [8]. The showers differ in several details; however our far-field calculation of the pulse from a shower gives the same result up to a GHz frequency as that of [8] when both are applied to the same shower simulation. This has been checked explicitly by calculating the field using our field code and the track information from ZHS code with the direct field output from ZHS code for the same shower. The differences between a GEANT and a ZHS shower of initial energy 100 GeV is summarized in Table II. The origin of differences between the two Monte Carlos is under study.

---

**FIGURE 4.** (a) $(dE/dx)_{ionization}$ calculated from GEANT output. The average is over 500 electron tracks with 0.1 MeV kinetic energy threshold. We also show theoretical Bethe-Bloch curve. (b) Electromagnetic pulses from cascades in ice generated by GEANT. Pulse height scales linearly and pulse width scales inversely with primary energy. Fraunhofer limit has been taken to calculate field.
Our direct calculation of Moliere radius, critical energy and shower population as a function of shower depth using GEANT all agree within a few percent with measurements or with published EGS4 simulations for iron and lead [15]. The extension to ice is straightforward and we expect the same level of reliability here.

Our results agree with the theoretically expected [16] linear scaling of number of particles at shower maximum and logarithmic scaling of depth at shower maximum with energy. These are not straightforward results, since the theoretical predictions are based on inclusion of bremsstrahlung and pair production only, while the physics at the shower maximum is not dominated by these processes. It includes important contributions from Compton, Bhabha and Moller processes as well, which give rise to charge imbalance and, consequently, coherent radio Cherenkov field emission.
