Abstract

The neutrinoless double beta decay ($0\nu\beta\beta$-decay) transition to the first excited $0^{+}$ collective final state is examined for $A=76, 82, 100$ and 136 nuclei by assuming light and heavy Majorana neutrino exchange mechanisms as well as the trilinear R-parity violating contributions. Realistic calculations of nuclear matrix elements have been performed within the renormalized Quasi-particle Random Phase Approximation. Transitions to the first excited two-quadrupole phonon $0^{+}$ state are described within a boson expansion formalism and alternatively by using the operator recoupling method. We present the sensitivity parameters to different lepton number violating signals, which can be used in planning the $0\nu\beta\beta$-decay experiments. The half-life of $0\nu\beta\beta$-decay to the first excited state $0^{+}_{1}$ is by a factor of 10 to 100 larger than that of the transition to the ground state, $0^{+}_{g.s.}$.

PACS numbers:23.40.BW, 23.40.HC
I. INTRODUCTION

The neutrinoless double beta decay (0νββ-decay), which violates the total lepton number by two units, is the most sensitive low-energy probe for physics beyond the standard model (SM) [1–5]. The observation of the 0νββ-decay would provide unambiguous evidence that at least one of the neutrinos is a Majorana particle with non-zero mass [6]. This conclusion is valid without specifying which from the plethora of possible 0νββ-decay mechanisms triggered by exchange of neutrinos, neutralinos, gluinos, leptoquarks etc is the leading one. The current experimental upper limits on the 0νββ-decay half-life impose stringent constraints, e.g., on the parameters of Grand Unification (GUT) and supersymmetric (SUSY) extensions of the SM.

There is a continuous, both experimental and theoretical, activity in the field of 0νββ-decay. An interesting issue is what are the implications of the neutrino oscillation phenomenology to the 0νββ-decay. We note that the results of the solar [7], atmospheric [8] and terrestrial [9] neutrino experiments provide a convincing evidence of neutrino oscillations, which require non-vanishing masses for neutrinos as well as neutrino mixing [10]. The neutrino oscillations are sensitive to the differences of the masses squared and cannot distinguish between Dirac and Majorana neutrinos. Nevertheless, if assumptions about the character (Dirac or Majorana neutrinos), the phases and the neutrino mixing pattern are considered, one can derive estimates for the effective Majorana electron neutrino mass $<m_\nu>$ responsible for 0νββ-decay. The current viable analysis implies the effective neutrino mass $<m_\nu>$ to be within the range $10^{-3} \, eV \leq <m_\nu> \leq 1 \, eV$ [11,12]. The present generation of 0νββ-decay experiments [13–15] achieve sensitivities of $T_{1/2}^{0\nu} \sim 10^{24} - 10^{25}$ years for different isotopes [13–15]. It corresponds to $<m_\nu> \approx 0.5 - 1. \, eV$ [16,17], i.e., these 0νββ-decay experiments allow already to discriminate among various neutrino mixing schemes.

The neutrino oscillations imply that perhaps we are close to the observation of the 0νββ-decay. This would be a major achievement. Maybe it is enough to increase the sensitivity to $<m_\nu>$ by about an order of magnitude, i.e., the 0νββ-decay experiments should be
sensitive to half-lifes of $10^{27} - 10^{28}$ years for the ground to ground transitions. We hope that these data will stimulate new experimental activities. Ambitious plans are underway to push the upper constraints on lepton number violating parameters further down. By using several tons of enriched $^{76}\text{Ge}$, the GENIUS experiment is expected to probe $<m_{\nu}>$ up to $10^{-2}$ eV [18]. The CUORE experiment intends to search for rare events with the help of a cryogenic $\text{TeO}_2$ detector with high energy resolution [19]. The ongoing NEMO 3 experiment, now under construction in the Fréjus underground laboratory, will measure up to 10 kg of different double beta decay isotopes [20]. Both CUORE and NEMO 3 have a chance to reach a sensitivity to the effective neutrino mass $<m_{\nu}>$ in the order of 0.1 eV [17]

It is worth to examine also other possibilities to increase the sensitivity of 0$\nu$ββ-decay experiments. Till now, the attention was concentrated mostly to the 0$\nu$ββ-decay transition to the ground state of the final nucleus. However, there might be a chance that the transitions to the excited 0$^+$ and/or 2$^+$ final states are more favorable experimentally, at least for a particular mechanism for the 0$\nu$ββ-decay [15,21]. Generally speaking, transitions to the excited states are suppressed due to the reduced $Q_{\beta\beta}$ value. However, this restriction can be compensated by a possible lower background due to a coincidence of the $\beta$ particles with the $\gamma$ or $\gamma'$s from the excited final state. The possible advantage depends on the ratio of corresponding nuclear matrix elements to the excited and to the ground state. If their values are comparable, the 0$\nu$ββ-decay experiment measuring transitions to ground and excited final states could be of a similar sensitivity.

Recently, this issue received an increasing attention from many experts in the field. The 0$\nu$ββ-decay of $^{76}\text{Ge}$ and $^{100}\text{Mo}$ to the first excited 2$^+_1$ final state has been investigated in Ref. [22] by assuming massive Majorana neutrinos and right-handed weak currents. It was found that the zero neutrino double beta decay transition probabilities for the $0^+ \rightarrow 2^+$ decay are strongly suppressed due to higher partial waves of the emitted electrons needed in the $0^+ \rightarrow 0^+_{g.s.}$ transition. But in the case of the 0$\nu$ββ-decay to lowest and first excited 0$^+$ states the two emitted electrons are preferentially in a $s_{1/2}$ wave. Therefore, this decay channel is
more favored. Recently, the first realistic calculation for $0^+ \rightarrow 0^+_1$ decay has been performed for $A=76$ and 82 nuclei within a higher Quasiparticle Random Phase Approximation (QRPA) [23]. The $0\nu\beta\beta$-decay mechanisms mediated by light Majorana neutrinos within the left-right symmetric model have been discussed. The conclusion was that the transition to excited collective $0^+$ final states are reduced compared with the decay to the ground state. It would be worthwhile to test this result also within other nuclear approaches.

The aim of this work is to examine the $0\nu\beta\beta$-decay of $^{76}Ge$, $^{82}Se$, $^{100}Mo$ and $^{136}Xe$ to the first excited $0^+_1$ state. We shall discuss the mechanisms induced by light and heavy Majorana neutrino exchange as well as those with trilinear R-parity violation. The nuclear matrix elements will be evaluated within the renormalized QRPA (RQRPA) [24,25], which take into account the Pauli exclusion principle. We shall also consider the contributions to $0\nu\beta\beta$-decay coming from the momentum-dependent induced nucleon currents, which has been found to be significant for ground state to ground state transitions [16]. We note that this contributions were ignored in a similar study [23]. The collective two-quadrupole phonon state $0^+_1$, will be described by two different approaches proposed in Refs. [26] and [27–29], respectively. Finally the sensitivity parameters for a given isotope, associated with different lepton number violating signals and nuclear transitions, will be calculated. Also a discussion about possible projects of future experimental searches for $0\nu\beta\beta$-decay to excited final states $0^+$, will be presented.

The paper is organized as follows. In section II, basic formulae relevant to the $0\nu\beta\beta$-decay mechanisms, are presented. In section III two approaches meant to calculate the transitions to ground and excited states, are described. In section IV we calculate the $0\nu\beta\beta$-decay matrix elements for $A=76, 82, 100$ and $136$ nuclei via RQRPA. We also determine the sensitivity of transitions to the collective excited state $0^+_1$, to lepton number violation associated with the Majorana neutrino mass and R-parity breaking. The perspectives of measuring $0^+ \rightarrow 0^+_1$ decays are analyzed. The summary and final conclusions are presented in Sec. IV.
II. THE $0\nu\beta\beta$-DECAY HALF-LIFE

The theory of light and heavy Majorana neutrino mass modes of $0\nu\beta\beta$-decay have been reviewed, e.g., in Refs. [1,2,4,16]. The trilinear R-parity violating mode of $0\nu\beta\beta$-decay has been presented in Refs. [30–33]. Without going into details of derivations, we summarize the basic ingredients of these modes of $0\nu\beta\beta$-decay.

A. Majorana neutrino mass mechanism

The half-life of $0\nu\beta\beta$-decay associated with light and heavy Majorana neutrino mass mechanism is given as

$$[T_{1/2}^{0\nu}]^{-1} = G_{01} \left| \frac{<m_\nu>}{m_e} M_{<m_\nu>}^{\text{light}} + \eta_N M_{\eta N}^{\text{heavy}} \right|^2. \quad (2.1)$$

Here, $G_{01}$ is the integrated kinematical factor [1,34]. The lepton number non-conserving parameters, i.e., the effective electron Majorana neutrino mass $<m_\nu>$ and $\eta_N$, are given as follows:

$$<m_\nu> = \sum_1^3 (U_{e k}^L)^2 \xi_k m_k, \quad \eta_N = \sum_1^3 (U_{e k}^L)^2 \Xi_k \frac{m_p}{M_k}, \quad (2.2)$$

with $m_p$ ($m_e$) being the proton (electron) mass. $U^L$ is the unitary mixing matrix connecting left-handed neutrino weak eigenstates $\nu_{lL}$, to mass eigenstates of light $\chi_k$ and heavy $N_k$ Majorana neutrinos with masses $m_k$ ($m_k << 1 \text{ MeV}$) and $M_k$ ($M_k >> 1 \text{ GeV}$), respectively. We have

$$\nu_{lL} = \sum_{k=\text{light}} U^L_{lk} \chi_{kL} + \sum_{k=\text{heavy}} U^L_{lk} N_{kL} \quad (l = e, \mu, \tau). \quad (2.3)$$

$\nu_k, N_k$ satisfy the Majorana condition: $\nu_k \xi_k = C \Theta_k^T, \quad N_k \Xi_k = C \Theta_k^T$, where $C$ denotes the charge conjugation while $\xi, \Xi$ are phase factors; the eigenmasses are assumed positive.

The nuclear matrix elements associated with the exchange of light ($M_{<m_\nu>}^{\text{light}}$) and heavy neutrinos ($M_{\eta N}^{\text{heavy}}$), including contributions from induced nucleon currents can be written as a sum of Fermi, Gamow-Teller and tensor components [16]:
\[ M_K = \frac{-M_F^\kappa}{g_A^2} + M_{GT}^\kappa + M_T^\kappa \quad (\kappa = < m_\nu >, \eta_N). \]  

(2.4)

Here, \( g_A = 1.25 \). Using the second quantization formalism, \( M_K \) can be expressed in terms of relative coordinates as follows:

\[
M_K = \sum_{J^*} \sum_{j_n,j_n'} (-)^{j_n+j_n'+J+J}(2J + 1) \begin{pmatrix} j_p & j_n & J \\ j_p' & j_n' & J \end{pmatrix} \times \langle p(1), p'(2); J | f(r_{12}) \pi_1^+ \pi_2^+ O_K(12) f(r_{12}) | n(1), n'(2); J \rangle \\
\times \langle 0^+_f | [c_p^+ c_{n'}]_J | J^\pi m_f \rangle \langle J^\pi m_i | [c_p^+ c_n]_J | 0^+_i \rangle. \quad (2.5)
\]

Here, \( f(r_{12}) \) is the short-range correlation function [4] and \( O_K(12) \) (\( \kappa = < m_\nu >, \eta_N \)) represents the coordinate and spin dependent part of the two-body 0\( \nu \beta \beta \)-decay transition operator

\[
O_K(12) = -\frac{H_F^\kappa(r_{12})}{g_A^2} + H_{GT}^\kappa(r_{12}) \sigma_{12} + H_T^\kappa(r_{12}) S_{12}. \quad (2.6)
\]

Also, the following notations have been used:

\[
\mathbf{r}_{12} = \mathbf{r}_1 - \mathbf{r}_2; \quad r_{12} = |\mathbf{r}_{12}|, \quad \hat{\mathbf{r}}_{12} = \frac{\mathbf{r}_{12}}{r_{12}};
\]

\[
S_{12} = 3(\vec{\sigma}_1 \cdot \hat{\mathbf{r}}_{12})(\vec{\sigma}_2 \cdot \hat{\mathbf{r}}_{12}) - \sigma_{12}, \quad \sigma_{12} = \vec{\sigma}_1 \cdot \vec{\sigma}_2. \quad (2.7)
\]

where \( \mathbf{r}_1 \) and \( \mathbf{r}_2 \) are coordinates of the beta decaying nucleons. The radial part of the light and heavy neutrino exchange potentials \( H_I^{<m_\nu>}(r_{12}) \) and \( H_I^{\eta_N}(r_{12}) \) (\( I = F, GT, T \)) can be written as

\[
H_I^{<m_\nu>}(r_{12}) = \frac{2}{\pi g_A^2 r_{12}} \int_0^\infty \frac{sin(q r_{12})}{q + E^m(J) - (E^i + E^f)/2} h_I(q^2) dq, \\
H_I^{\eta_N}(r_{12}) = \frac{1}{m_p m_e \pi g_A^2 r_{12}} \int_0^\infty sin(q r_{12}) h_I(q^2) q dq \quad (2.8)
\]

with

\[
h_F(q^2) = g_V^2(q^2) g_A^2, \\
h_{GT}(q^2) = g_A^2(q^2) + \frac{1}{3} \frac{g_P^2(q^2) q^4}{4 m_p^2} - \frac{2}{3} \frac{g_A(q^2) g_P(q^2) q^2}{2 m_p} + \frac{2}{3} \frac{g_M^2(q^2) q^2}{4 m_p^2}, \\
h_T(q^2) = \frac{2}{3} \frac{g_A(q^2) g_P(q^2) q^2}{2 m_p} - \frac{1}{3} \frac{g_P^2(q^2) q^4}{4 m_p^2} + \frac{1}{3} \frac{g_M^2(q^2) q^2}{4 m_p^2}. \quad (2.9)
\]
Here, $R = r_0 A^{1/3}$ is the mean nuclear radius [16] with $r_0 = 1.1$ fm. $E^i$, $E^f$ and $E^m(J)$ are the energies of the initial, final and intermediate nuclear states with angular momentum $J$, respectively. The momentum dependence of the vector, weak magnetism, axial-vector and pseudoscalar formfactors ($g_V(q^2)$, $g_M(q^2)$, $g_A(q^2)$ and $g_P(q^2)$) can be found in Ref. [16].

We note that the overlap factor $\langle J^π m_f | J^π m_i \rangle$ and the one-body transition densities $< J^π m_i \parallel [c^+ p \bar{c}]_J \parallel 0^+_i >$ and $< 0^+_f \parallel [c^+_p \bar{c}]_J \parallel J^π m_f >$ entering Eq. (2.5) must be computed in a nuclear model.

**B. The trilinear R-parity violating mechanisms**

The minimal supersymmetric standard model (MSSM), which is the simplest extension of the SM, preserves the R-parity, i.e., also the total lepton number. We remind that R-parity is a discrete multiplicative symmetry defined as $R_p = (-1)^{3B+L+2S}$, where $S$, $B$ and $L$ are the spin, the baryon and the lepton quantum number. Thus $R_p = +1$ for SM particles and $R_p = -1$ for superpartners.

Generally, one can add trilinear R-parity violating terms to the superpotential of MSSM

$$W_{R_p} = \lambda_{ijk} L_i L_j E^c_k + \lambda'_{ijk} Q_j D^c_k + \mu_j L_j H_2 + \lambda''_{ijk} U^c_i D^c_j D^c_k,$$

where $i, j, k$ denote generation indices. Here $L, Q$ stand for the lepton and quark doublet left-handed superfields while $E^c$, $U^c$, $D^c$ for the charge conjugated lepton, up and down quark singlet superfields, respectively. The terms proportional to $\lambda$ and $\lambda'$ violate the lepton number while those proportional to $\lambda''$ violate the baryon number.

The $0\nu\beta\beta$-decay can be induced by different trilinear R-parity violating mechanisms, partially determined by different products of the parameters $\lambda$ and $\lambda'$ [12,33,35]. Here, we consider those mechanisms which lead to the most stringent constrain on the $\lambda'_{111}$ parameter. They are triggered by exchange of gluinos and neutralinos. The corresponding Feynman diagrams can be found, e.g., in Ref. [17,33]. If the masses of the SUSY particles are assumed to be of about the same value, there is a dominance of the gluino-exchange mechanism [33].
This conclusion is expected to be valid also for the $0\nu\beta\beta$-decay transitions to excited $0^+$ states.

The $0\nu\beta\beta$-decay half-life, associated with exchange of gluinos, is [4,33]

$$[T_{1/2}(0^+ \rightarrow 0^+)]^{-1} = G_{01} |\eta_\tilde{g} + 4\eta'_\tilde{g}|^2 |\mathcal{M}_\chi_{111}|^2. \quad (2.11)$$

The effective $R_p$-violating parameters $\eta_\tilde{g}$ and $\eta'_\tilde{g}$ can be expressed by means of the fundamental parameters of the MSSM, as follows:

$$\eta_\tilde{g} = \frac{\pi \alpha_s}{6} \frac{\lambda_{111}^2}{G_F m_{\tilde{g}}^4} \left[ 1 + \left( \frac{m_{\tilde{d}_R}}{m_{\tilde{u}_L}} \right)^4 \right],$$

$$\eta'_\tilde{g} = \frac{\pi \alpha_s}{12} \frac{\lambda_{111}^2}{G_F m_{\tilde{g}}^4} \left( \frac{m_{\tilde{d}_R}}{m_{\tilde{u}_L}} \right)^2. \quad (2.12)$$

Here, $\alpha_s = g_s^2/(4\pi)$ is the SU(3)$_c$ gauge coupling constant. $m_{\tilde{u}_L}$, $m_{\tilde{d}_R}$ and $m_{\tilde{g}}$ are masses of the u-squark, d-squark and the gluino.

At the level of hadronization, the dominant mechanism is the pion realization of the underlying $\Delta L = 2$ quark-level $0\nu\beta\beta$-transition $dd \rightarrow uu + 2e^-$ [33]. The nuclear matrix element $\mathcal{M}_\chi_{111}$ can be written as a sum of contributions originating from one and two pion–exchange modes. Thus, we have [33]

$$\mathcal{M}_\chi_{111} = \mathcal{M}^{1\pi} + \mathcal{M}^{2\pi}$$

$$= \left( \frac{m_A}{m_p} \right)^2 \frac{m_p}{m_e} \left( \frac{4}{3} \alpha^{1\pi} (M^{1\pi}_{GT} + M^{1\pi}_T) + \alpha^{2\pi} (M^{2\pi}_{GT} + M^{2\pi}_T) \right). \quad (2.13)$$

where

$$M^{k\pi}_{GT} = \langle 0^+_f | \sum_{i \neq j} \tau^+_i \tau^+_j \bar{\sigma}_i \cdot \bar{\sigma}_j F^{(k)}_{GT}(m_{\pi r}) \frac{R}{r_{ij}} | 0^+_i \rangle, \quad \text{with} \quad k = 1, 2$$

$$M^{k\pi}_T = \langle 0^+_f | \sum_{i \neq j} \tau^+_i \tau^+_j [3(\bar{\sigma}_i \cdot \hat{r}_{ij})(\bar{\sigma}_j \cdot \hat{r}_{ij}) - \bar{\sigma}_i \cdot \bar{\sigma}_j] F^{(k)}_T(m_{\pi r}) \frac{R}{r_{ij}} | 0^+_i \rangle. \quad (2.14)$$

with

$$F^{(1)}_{GT}(x) = e^{-x}, \quad F^{(1)}_T(x) = (3 + 3x + x^2) \frac{e^{-x}}{x^2}, \quad (2.15)$$

$$F^{(2)}_{GT}(x) = (x-2)e^{-x}, \quad F^{(2)}_T(x) = (x+1)e^{-x}. \quad (2.16)$$
Here, $m_A (= 850 \, MeV)$ and $m_\pi$ are the mass scale of nucleon formfactor and the mass of the pion, respectively. Values of the structure coefficients $\alpha^{k\pi}$ (k=1,2) are [33]: $\alpha^{1\pi} = -4.4 \times 10^{-2}$, $\alpha^{2\pi} = 2 \times 10^{-1}$.

Having in mind the forthcoming calculations within the RQRPA, it is useful to rewrite $\mathcal{M}_{\lambda'_{111}}$ in the form given by Eqs. (2.5) and (2.6) ($\mathcal{K} = \lambda'_{111}$). One finds that the Fermi part of the pion–exchange potential is equal to zero ($H^\lambda_{\mathcal{K}^*} (r_{12}) = 0$) and the the Gamow-Teller and tensor parts are given by:

$$H^\lambda_{\mathcal{K}^*} (r_{12}) = \left( \frac{m_A}{m_p} \right)^2 \frac{m_\pi}{m_e} \left( \frac{4}{3} \alpha^{1\pi} F^{1\pi}_{GT}(r_{12}^*) + \alpha^{2\pi} F^{2\pi}_{GT}(r_{12}^*) \right),$$

$$H^\lambda_{\mathcal{T}} (r_{12}) = \left( \frac{m_A}{m_p} \right)^2 \frac{m_\pi}{m_e} \left( \frac{4}{3} \alpha^{1\pi} F^{1\pi}_{T}(r_{12}) + \alpha^{2\pi} F^{2\pi}_{T}(r_{12}) \right).$$

### III. ONE–BODY TRANSITION DENSITIES

The nuclear matrix element $\mathcal{M}_{\mathcal{K}}$ ($\mathcal{K} = < m_\nu >, \eta_N \lambda'_{111}$), in Eq. (2.5), is associated with the $0\nu\beta\beta$-decay to the ground state, $0_g^+\text{g.s.}$, or to any of the excited $0^+$ states in the final nucleus. Its evaluation requires the description of the initial ($|0^+_i\rangle$), final ($|0^+_f\rangle$) and the intermediate states (all in different nuclei) with angular momentum and parity $J^\pi_i$ ($|J^\pi_{m_{i,f}}\rangle$), within a given nuclear model. Then, the one-body transition density, entering the expression for $\mathcal{M}_{\mathcal{K}}$, can be calculated and consequently the chosen matrix element is readily obtained.

The standard QRPA (based on the quasiboson approximation) and the RQRPA have been intensively used to calculate nuclear matrix elements for the double beta decay [4,16,23–25,32–34]. The RQRPA includes anharmonicities (the ground state is less correlated than in the standard QRPA) and there is no collapse of its first solution within the physical range of the particle-particle interaction strength. Within schematic models, it has been shown that by including the Pauli Exclusion Principle (PEP) in the QRPA, good agreement with the exact solution of the many-body problem can be achieved even beyond the critical point of the standard QRPA [36]. The RQRPA takes into account the PEP in an approximate way. Nevertheless, it is enough to avoid the main drawback of the
standard QRPA and to reduce the sensitivity of the calculated observables to the details of the nuclear model. The RQRPA has been used in our previous studies of the double beta decay [4,16,29,32,33,37]. Here we apply this approach to calculate the $0\nu\beta\beta$-decay to first excited states $0^+$. 

The final nuclei for $A = 76, 82, 100$ and $136$ double beta decaying systems are $^{76}$Se, $^{82}$Kr, $^{100}$Ru and $^{136}$Ba, respectively. The first excited $0^+_1$ state of these nuclei is believed to be member of the vibrational triplet $0^+, 2^+, 4^+$. This state can be described as follows

$$|0^+_1\rangle = \frac{1}{\sqrt{2}} \{ \Gamma_2^{1\dagger} \otimes \Gamma_2^{1\dagger} \} |0^+_{g.s.}\rangle,$$  \hspace{1cm} (3.1)

where $\Gamma_2^{1\dagger}$ is the creation quadrupole phonon operator. The experimental energies of $0^+_1$ ($E(0^+_1)$) and $2^+_1$ ($E(2^+_1)$) states relative to the ground state energies are

$$[E(0^+_1), E(2^+_1)] = [1.122, 0.559] \text{ MeV for } A = 76,$$

$$= [1.488, 0.777] \text{ MeV for } A = 82,$$

$$= [1.130, 0.540] \text{ MeV for } A = 100,$$

$$= [1.579, 0.818] \text{ MeV for } A = 136. \hspace{1cm} (3.2)$$

One notices that the energy of the $0^+_1$ excited state is about twice the energy of the $2^+_1$ excited state.

The nuclear states of interest are described as charge changing (pn-RQRPA) and charge conserving (ppnn-RQRPA) modes of the RQRPA approach.

In the framework of the pn-RQRPA, the $m^{th}$ excited state of the intermediate odd-odd nucleus, with the angular momentum $J$ and the projection $M$, is created by applying the phonon-operator $Q_{JM^*}^{m\dagger}$ on the vacuum state $|0^+_{RPA}\rangle$:

$$|m, JM^*\rangle = Q_{JM^*}^{m\dagger}|0^+_{RPA}\rangle \quad \text{with} \quad Q_{JM^*}^{m\dagger}|0^+_{RPA}\rangle = 0. \hspace{1cm} (3.3)$$

Here $|0^+_{RPA}\rangle$ is the ground state of the initial or the final nucleus and the phonon-operator $Q_{JM^*}^{m\dagger}$ is defined by the ansatz:

$$Q_{JM^*}^{m\dagger} = \sum_{pn} \left[ X_{(pn,J^*)}^m A^{\dagger}(pn, JM) + Y_{(pn,J^*)}^m \tilde{A}(pn, JM) \right]. \hspace{1cm} (3.4)$$
$X^{m}_{(pm, J^e)}, Y^{m}_{(pm, J^e)}$ denotes free variational amplitudes, which are calculated by solving the RQRPA equations.

The first excited $2^+$ state of the daughter nucleus is assumed to have one quadrupole-phonon character. Within the ppnn-RQRPA (allowing for two proton and two neutron quasiparticle excitations only) this state is defined by:

$$|2^+_1\rangle = \Gamma_{2M^+}^1|0^+_RPA\rangle \quad \text{with} \quad \Gamma_{2M^+}^1|0^+_RPA\rangle = 0,$$

where

$$\Gamma_{2M^+}^1 = \sum_{p \leq p'} \left[ R_{(p,p',2^+)}^1 A(p, p', 2M) + S_{(p,p',2^+)}^1 \tilde{A}(p,p',2M) \right] + \sum_{n \leq n'} \left[ R_{(n,n',2^+)}^1 A(n, n', 2M) + S_{(n,n',2^+)}^1 \tilde{A}(n,n',2M) \right].$$

$A^\dagger(\tau\tau', JM)$ and $A(\tau\tau', JM)$ ($\tau = p, n$ and $\tau' = p', n'$) are the two quasi-particle creation and annihilation operators coupled to the good angular momentum $J$ with projection $M$ respectively, defined by:

$$A^\dagger(\tau\tau', JM) = \frac{(1 + (-1)^J \delta_{\tau\tau'})}{(1 + \delta_{\tau\tau'})^{3/2}} \sum_{m, m'} C^{JM}_{j m, j' m'} a^\dagger_{\tau m} a^\dagger_{\tau' m'},$$
$$A(\tau\tau', JM) = (A^\dagger(\tau\tau', JM))^\dagger.$$ (3.7)

The vacua defined by Eqs. (3.5) and (3.3) are in principle different from each other. However the differences induce corrections to the matrix elements considered, of higher order and therefore they are neglected. The quasiparticle creation and annihilation operators ($a^\dagger_{\tau m}, a_{\tau m}$, $\tau = p, n$) have been defined through the Bogoliubov-Valatin transformation

$$\begin{pmatrix} a^\dagger_{\tau m} \\ \tilde{a}_{\tau m} \end{pmatrix} = \begin{pmatrix} u_\tau & v_\tau \\ -v_\tau & u_\tau \end{pmatrix} \begin{pmatrix} c^\dagger_{\tau m} \\ \tilde{c}_{\tau m} \end{pmatrix},$$

where $c^\dagger_{\tau m}$ ($c_{\tau m}$) denotes the particle creation (annihilation) operator acting on a single particle level with quantum numbers $(n_\tau, l_\tau, j_\tau)$. The parameters $u, v$ are occupation amplitudes and the tilde symbol indicates the time-reversal operation, e.g. $\tilde{a}_{\tau m} = (-1)^{j_\tau - m_\tau} a_{\tau - m_\tau}$.

Let us now denote by $D_{pm}$ and $D_{\tau\tau'}$ ($\tau = p, n$) the following expectation values:
\[ \langle 0^+_{RPA} | [A(pn, JM), A^\dagger(p'n', JM)] | 0^+_{RPA} \rangle = \delta_{pp'}\delta_{nn'}D_{pn}, \]
\[ \langle 0^+_{RPA} | [A(\tau \tau', JM), A^\dagger(\sigma \sigma', JM)] | 0^+_{RPA} \rangle = (\delta_{\tau \sigma}\delta_{\tau' \sigma'} - (-1)^{j_\tau + j_\tau'-1}\delta_{\tau \sigma'}\delta_{\tau' \sigma})D_{\tau \tau'}. \] (3.9)

Here, the exact expressions of the commutators are taken into account. The calculation of \( D \) factors is discussed in Ref. [25,38].

Solving the pn-RQRPA (ppnn-RQRPA) equations, one gets the renormalized amplitudes \( X, Y (R, S) \) with the usual normalization \( XX - YY = 1 \) \( (RR - SS = 1) \). They are related with \( X (R) \) and \( Y (S) \) amplitudes, characterizing the standard QRPA phonon operator by:

\[ \begin{align*}
X^m_{(pn,J^\pi)} &= \sqrt{D_{pn}}X^m_{(pn,J^\pi)}, \\
Y^m_{(pn,J^\pi)} &= \sqrt{D_{pn}}Y^m_{(pn,J^\pi)}, \\
R^m_{(\tau \tau',J^\pi)} &= \sqrt{D_{\tau \tau'}}R^m_{(\tau \tau',J^\pi)}, \\
S^m_{(\tau \tau',J^\pi)} &= \sqrt{D_{\tau \tau'}}S^m_{(\tau \tau',J^\pi)}. \end{align*} \] (3.10)

In the quasiparticle representation, the beta transition density operator can be written as:

\[ [c_p^+ c_n^]_{JM} = u_p v_n A^\dagger(pn, JM) + u_n v_p \bar{A}(pn, JM) \]
\[ + u_p u_n B^\dagger(pn, JM) - v_p v_n \bar{B}(pn, JM). \] (3.11)

If we restrict our consideration to the ground state to ground state \( 0\nu\beta\beta \)-decay we end up with the following expressions for one-body densities [16,25]

\[ < J^\pi m_i | [c_p^+ c_n^]_{J} | 0^+_i > = \sqrt{2J + 1}(u_p^{(i)} v_n^{(i)} X^m_{(pn,J^\pi)} + v_p^{(i)} u_n^{(i)} Y^m_{(pn,J^\pi)})\sqrt{D_{pn}}. \] (3.12)
\[ < 0^+_f | [c_p^+ c_n^]_{J} | J^\pi m_f > = \sqrt{2J + 1}(u_p^{(f)} v_n^{(f)} X^m_{(pn,J^\pi)} + u_p^{(f)} v_n^{(f)} Y^m_{(pn,J^\pi)})\sqrt{D_{pn}}. \] (3.13)

Here, the index \( i (f) \) indicates that the quasiparticles and the excited states of the nucleus are defined with respect to the initial (final) nuclear ground state \( |0^+_i \rangle \) \( (|0^+_f \rangle \). The overlap matrix elements entering Eq. (2.5) are explicitly given in Ref. [39].

The beta transition density from the intermediate states \( |J^\pi m \rangle \) to the first excited \( 0^+ \) state of the daughter nucleus, which is considered to be of two-quadrupole phonon character for the nuclei with \( A=76, 82, 100 \) and 136, can be written as:

\[ \langle 0^+_i | [c_p^+ c_n^]_{J} | J^\pi m \rangle = \langle 0^+_{RPA} | \frac{1}{\sqrt{2}} \{ \Gamma_2 \otimes \Gamma_2 \}^0 \{ [c_p^+ c_n^]_{J} \otimes Q^m_{J^\pi} \}^0 | 0^+_{RPA} \rangle \sqrt{2J + 1}, \] (3.14)

\[ 12 \]
There are two basic approaches to calculate this expression. We shall discuss them in the next sections.

**A. The recoupling approach**

The first calculation of the two-neutrino double beta decay \(2\nu\beta\beta\)-decay transition to an excited \(0^+\) final state, was presented in Ref. [26]. The formalism proposed was developed in the Tamm-Dancoff approximation (TDA). It was claimed that the contribution coming from the backgoing graphs are negligible. The dominant contribution is obtained by calculating, through a recoupling procedure, the scalar product of two pairs of proton-neutron quasiparticle creation operators, originating from the beta transition \(\tilde{c}_p c_n\) and the phonon \(Q_{JM}^{m_f}\) operators.

\[
\{A^\dagger(pn, J) \otimes A^\dagger(p'n', J)\}^0 = -\sum_{J'}(-1)^{j_n+j_p'+J+J'} \frac{(\delta_{pp'}(-)J' + 1)}{(1 + \delta_{pp'})^{1/2}} \frac{(\delta_{nn'}(-)J' + 1)}{(1 + \delta_{nn'})^{1/2}} \times (2J' + 1)^{1/2} \left\{ \begin{array}{c} j_n \cr j_p \cr j_n' \cr j_p' \end{array} \right\} \{A^\dagger(pp', J') \otimes A^\dagger(nn', J')\}^0 \tag{3.15}
\]

Henceforth we shall denote this approach as recoupling method (RCM).

By using Eq. (3.14), the beta transition matrix element takes the form

\[
\langle 0^+_\pi | c_p^+ \tilde{c}_n_{JM} | J^\pi M, m_f \rangle = \sqrt{\frac{10}{2}} \sum_{p'n'} (1 + \delta_{pp'})^{1/2} (1 + \delta_{nn'})^{1/2} \left( \frac{D_{pp'}^{(f)} D_{mm'}^{(f)}}{D_{pn}^{(f)}} \right)^{1/2} \times \left\{ \begin{array}{c} j_n \cr j_p \cr j_n' \cr j_p' \end{array} \right\} \left( u_p^{(f)} v_n^{(f)} X_{(p'n',J^\pi)} R_{pp',2+}^{m_f} R_{nn',2+}^{m_f} - v_p^{(f)} u_n^{(f)} Y_{(p'n',J^\pi)} R_{pp',2+}^{m_f} S_{nn',2+}^{m_f} \right).
\tag{3.16}
\]

Obviously, in the above expression, the full expression of the RPA phonon operator was used. In comparing this transition density to \(0^+_\pi\) with that one leading to the ground state, we find two important differences. First, the dominant contribution in Eq.(3.16) is a product of three forward-going amplitudes. This fact implies that the transition amplitude is not expected to be very sensitive to the nuclear ground state correlations. Second, the leading term in Eq. (3.16) is multiplied by the factor \(u_p^{(f)} v_n^{(f)}\) (i.e., “\(\beta^-\)” like) while the leading term of beta ground state transition in Eq. (3.13) contains the factor \(v_p^{(f)} u_n^{(f)}\) (i.e., “\(\beta^+\)” like).
The drawback of this approach is that the transition density, in Eq. (3.16), contains significant unphysical contributions. To clarify this point we transform the second part of the r.h.s. of Eq. (3.14), which up to a multiplicative constant should represent the excited state $0^+_1$ in the $(A,Z+2)$ nucleus. From the transition operator written in quasiparticle representation we keep, for illustration, the operator $A^\dagger(pn, J)$, which is further expressed in terms of the pnQRPA bosons. The final result is:

$$\{ A^\dagger(pn, J) \otimes Q_{J+}^{m_1} \} 0^+_1 |0_{RPA_J}^+\rangle = \sum_{m'} [X_{(pn,J^\pi)}^{m_1'} \{ Q_{J+}^{m_1'} \otimes Q_{J+}^{m_1} \} 0^+_1 |0_{RPA_J}^+\rangle \]

$$

The second term in the above equation, is obtained by using the commutator algebra for $Q_{J+}^{m_1}$ and its hermitian conjugate operator, and then Eq. (3.3). From Eq. (3.17) it follows that within the RCM procedure we have produced a linear combination of a state associated to the $(A,Z)$ nucleus and the ground state characterizing the $(A,Z+2)$ nucleus. We note that the desired $0^+_1$ excited state of $(A,Z+2)$ nucleus is missing. The RCM does not allow to eliminate the admixture of these states, which due to the recoupling procedure are related to the $0^+_1$ excited state. Moreover, it is worth noting that the component in the $(A,Z+2)$ nucleus is proportional to the Y-amplitude, as prescribed by the method presented in the next subsection, and not to the forward going amplitude of the proton-neutron dipole phonon as suggested by the RCM approach. Thus, the validity of this recoupling procedure is questionable in the framework of the QRPA.

The RCM has been modified by introducing a multiple commutator method (MCM) and applied to calculate different lepton-number conserving modes of the double beta decay [40]. This version of the RCM has been also used for describing the $0\nu\beta\beta$-decay to excited collective $0^+$ states [23].
The pioneering approach to study the double beta decay to excited states of the final nucleus was proposed in Refs. [27,28]. It is the so called boson expansion method (BEM). Applications of the BEM approach to study the single beta and $2^{\nu}\beta\beta$-decay to the first excited quadrapole state ($2^+_1$) and the two–quadrapole–phonon states ($0^+_{2-ph}, 2^+_2-ph$) of even–even isotopes were presented in Refs. [27,28]. Recently, the renormalized version of the BEM was applied to the transition $^{82}Se \rightarrow ^{82}Kr$ [29]. The new version has the virtue of exploiting the complementary features of the BEM and RQRPA methods. As a matter of fact this improved version of BEM is adopted in the present paper.

Within the BEM approach, the operators involved in the r.h.s. of Eq. (3.11) are written as polynomials of the RPA bosons [27,28], so that the mutual commutation relations are consistently preserved by the boson mapping. We shall follow this procedure with some simplifications, which do not influence the final form of the one–body transition density.

By exploiting the fact that $Q_m^0|0^+_RPA_f\rangle = 0$, we introduce a commutator in the expression for the one-body transition operator to the $0^+_1$ state. In addition, we evaluate this commutator by satisfying exact commutation relations. Thus we obtain

$$\langle 0^+_1|\tilde{B}^\dagger(\tau\tau,00)\rangle = \frac{\langle 0^+_1|B^\dagger(\tau\tau,00)|0^+_RPA_f\rangle}{\sqrt{(2j_{\tau} + 1)}}.$$  

We omitted the terms $A^\dagger(\tau\tau,00)$ and $A(\tau\tau,00)$, since in the boson expansion formalism they consist of terms comprising products of odd numbers of phonon operators $Q_{JM^*}^m, Q_{JM^*}^m, \Gamma_{2M^+}^1$, and $\Gamma_{2M^+}^1$, and consequently do not contribute to the above matrix element.

We proceed by performing the boson expansion of the operator $B^\dagger(\tau\tau,00)$ with the result

$$B^\dagger(\tau\tau,00) = B^{00}_{11}(\tau\tau)\{\Gamma_{2+}^{11} \otimes \Gamma_{2+}^{11}\}^0$$

$$+ B^{01}_{11}(\tau\tau)\{\Gamma_{2+}^{11} \otimes \Gamma_{2+}^{11}\}^0 + B^{11}_{11}(\tau\tau)\{\Gamma_{2+}^{11} \otimes \Gamma_{2+}^{11}\}^0.$$  

The upper indices, accompanying the expansion coefficients, indicate the number of the creation and annihilation phonon operators involved in the given terms while the lower
indices suggest that the phonon operators correspond to the first root of the ppn-QRPA equations. We note that relevant to the problem studied here is the coefficient $B_{11}^{20}(\tau \tau)$, which can be determined by the following procedure. Commuting Eq. (3.19) twice with $\Gamma_{21}^1$, and then taking the expectation value of the result in the boson vacuum, one obtains

$$B_{11}^{20}(\tau \tau) = \frac{1}{2} \sum_M C_{2M}^{00} \langle 0 | [\Gamma_{2M}^1, [\Gamma_{2-M}^1, B^\dagger(\tau \tau, 00)]]|0 \rangle \sum_{\tau'} \sum_{\tau''} \mathcal{R}_{(\tau'' \tau', 2+)}^1 \mathcal{S}_{(\tau'' \tau', 2+)}. \tag{3.20}$$

In the above equations, all commutators are exactly evaluated except for the last one for which the renormalized quasiboson approximation is used [27–29].

Now, by a straightforward calculation, one arrives at the final expression for the one-body transition density leading to the final excited $0^+_1$ two phonon state:

$$\langle 0^+_1 | [c_p^+ \tilde{c}_n^m J_M | J^M M, m_f \rangle = (v_{n_f}^p u_{n_f}^p \mathcal{X}_{(pn, J^M)}^m + u_{n_f}^p v_{n_f}^p \mathcal{Y}_{(pn, J^M)}^m) (\mathcal{D}_{pn})^{-1/2} \xi(p, p', n, n'), \tag{3.21}$$

where

$$\xi(p, p', n, n') = \sqrt{10} \left[ \frac{1}{2 j_n + 1} \left( \sum_{n' < n} \mathcal{R}_{(nn', 2+)}^1 \mathcal{S}_{(nn', 2+)}^1 + \mathcal{R}_{(n, n'+2)}^1 \mathcal{S}_{(n, n'+2)}^1 \right) \right] \frac{1}{2 j_p + 1} \left( \sum_{p' < p} \mathcal{R}_{(pp', 2+)}^1 \mathcal{S}_{(pp', 2+)}^1 + \mathcal{R}_{(p', p+2)}^1 \mathcal{S}_{(p', p+2)}^1 \right]. \tag{3.22}$$

It is worthwhile to notice that if we replace the factor $\xi(p, p', n, n')$ with unity and consider small ground state correlations, i.e. $\mathcal{D}_{pn} \simeq 1$, we obtain the ground state transition density from Eq. (3.13). We note that the transition density to the ground state is proportional to $(\mathcal{D}_{pn})^{1/2}$, i.e., it is suppressed by anharmonic effects, while the transition density to the excited $0^+_1$ state is proportional to $1/(\mathcal{D}_{pn})^{1/2}$, i.e., it is enhanced by large ground state correlations.

We remark that the BEM expression given in Eq. (3.21) differs considerably from the RCM expression given in Eq. (3.16). We see that the BEM transition density in Eq. (3.21) consists of products of forward and backward going variational amplitudes of the
ppnn-RQRPA. It means that the final result exhibits sensitivity to the particle-particle interaction of the nuclear Hamiltonian. In addition, the BEM transition amplitude is a \("\beta^+\) like amplitude since the leading term is proportional to \(u_v^f u_p^f\). This implies a possible strong dependence on the ground state correlations. The fact that the RCM and the MCM approaches differ considerably from the BEM procedure, when the final state is of multiple phonon character, was noticed already in Ref. [28]. The BEM avoids the operators recoupling and therefore the problem concerning the unphysical RCM contributions does not appear.

IV. NUMERICAL RESULTS AND DISCUSSIONS

The formalism described in the previous sections were applied to the transitions \( ^{76}Ge \rightarrow ^{76}Se \), \( ^{82}Se \rightarrow ^{82}Kr \), \( ^{100}Mo \rightarrow ^{100}Ru \) and \( ^{136}Xe \rightarrow ^{136}Ba \). The pn-RQRPA and the ppnn-RQRPA calculations have been performed for the same sets of basis-states as in Ref. [16], which are identical for protons and neutrons. The single particle energies were obtained by using a Coulomb corrected Woods Saxon potential. The realistic interaction employed is the Brueckner G-matrix of the Bonn one–boson exchange potential. The truncation of the single-particle space requires a renormalization of two–body matrix elements. The scaling of the pairing strength in the BCS calculation was adjusted to fit the empirical pairing gaps according to Ref. [41]. In the RQRPA calculations, the particle–particle and particle–hole channels of the G-matrix interaction are renormalized by multiplying them with the parameters \( g_{pp} \) and \( g_{ph} \), which, in principle, should be close to unity. Our adopted value for \( g_{ph} \) was \( g_{ph} = 0.8 \), as in our previous calculations [4,16]. We shall present the relevant nuclear matrix elements for \( g_{pp} = 1 \). Nevertheless, their sensitivity to \( g_{pp} \) within the interval 0.80-1.20, which can be regarded as physical, will be discussed. We note that in our calculations the pn-RQRPA and ppnn-RQRPA channels are coupled through the equation for the renormalization factors D [25]. Our numerical analysis shows that the quadrupole QRPA energies of the daughter nucleus are independent of \( g_{pp} \).

The results of our calculations are summarized in Tables I, II, IV and in Fig. 1. In Table
I the dimensionless nuclear matrix elements of light and heavy neutrino exchange modes of $0\nu\beta\beta$-decay of $^{76}$Ge, $^{82}$Se, $^{100}$Mo and $^{136}$Xe, are presented both for transitions to the ground and excited states. The displayed $0\nu\beta\beta$-decay matrix elements to the first excited states $0^+_1$, were obtained within the RCM and BEM approaches. The particular contributions to the full matrix elements coming from Fermi, Gamow-Teller and tensor terms in Eqs. (2.4) are shown as well. The modifications coming from induced nucleon currents are included in the Gamow-Teller and tensor components [16]. We find that the tensor contribution plays an important role when the mechanism is mediated by heavy neutrinos and tends to cancel the contributions by Fermi and Gamow-Teller transition amplitudes. By glancing at Table I we find that the nuclear matrix elements involving the first excited $0^+_1$ state are suppressed in comparison with those associated to transitions to the ground state. In the case of BEM calculations of $M_{<m
u>}$, the suppression factor is about 2.8, 2.8, 1.8 and 1.5 for A=76, 82, 100 and 136, respectively. The RCM values are close to the BEM ones for A=76, 82 and 100 nuclei. One notices an anomaly in the case of the A=136 system, where the RCM transition to the excited state is by a factor of 6.7 stronger than that to the ground state. It could be connected with the fact that $^{136}$Xe is a closed shell nucleus for neutrons (N=82) and therefore the unphysical contributions to this transition in the RCM approach might be larger. We note that it is not possible to compare directly nuclear matrix elements $M_{<m
u>}$ in Table I, with those calculated in Ref. [23] for A=76 and 82, since Ref. [23] does not include contributions from the induced currents. Nevertheless, we note that the ratio of the nuclear matrix elements of the transition to ground and excited states is equal to about 3, in Ref. [23]. This value is in good agreement with results of this article, despite the fact that the two formalisms differ from each other in many aspects.

From Table I it follows that the $0\nu\beta\beta$-decay, mediated by heavy neutrinos to excited final states for A = 76, 82 and 100 are weaker than those associated with ground state to ground state transitions, by about a factor of 1.3-2.0 ( 8-9 ) in the BEM (RCM). Here, the difference between the BEM and RCM predictions is more significant than for the light Majorana neutrino exchange mechanism. We note also that for the A=136 system, the RCM
value of $M_{\eta N}^{\text{heavy}}$ is comparable with the BEM one, i.e., within the RCM, the behavior of this nucleus is different from that of the remaining nuclei.

In Table II, the nuclear matrix elements associated with the trilinear R-parity violating mode of $0\nu\beta\beta$-decay are displayed. Both, the one pion- and two pion–exchange Gamow-Teller and tensor contributions to $M_{X_{111}}$ are shown. In Ref. [32,33], it was shown that there is a dominance of the two pion–exchange mode for the $0\nu\beta\beta$-decay transitions connecting the initial and final ground states, due to a larger structure coefficients $\alpha^{2\pi}$ and because of strong mutual cancelation of the one-pion exchange Gamow-Teller and tensor contributions. We see that the second reason does not hold in the case of transitions to $0_{1}^{+}$ excited states. We have found that the one-pion mode plays a more important role for this transition, giving a significant contribution to $M_{X_{111}}$. By comparing the values of nuclear matrix elements for ground and excited state transitions, we see that the second one is reduced by factor of 2.7-3.4 within the BEM. The RCM values are considerably smaller for A=76, 82 and 100 systems. A different situation is again found for the $0\nu\beta\beta$-decay of $^{136}$Xe where the RCM value is close to the BEM result.

One purpose of our study is also the sensitivity of results for $M_{X_{111}}^{\text{light}}, M_{\eta N}^{\text{heavy}}$ and $M_{X_{111}}$ to the details of the nuclear model. We have examined the $0\nu\beta\beta$-transition matrix elements as function of the renormalization factor for the strength of the particle–particle interaction, $g_{pp}$, considered in the physical interval (see Table III). We see that the BEM values for the transition to excited $0_{1}^{+}$ states exhibit a very similar dependence on $g_{pp}$, as those for the transitions to the ground state. On the other hand, the RCM values are insensitive to changes of $g_{pp}$. Thus, our expectations from the previous section, hinging on the forms of the BEM and RCM one-body transition densities, have been confirmed. We note that a similar behavior has been found also for other nuclear systems.

As it was already mentioned in the introduction there is additional suppression of the $0\nu\beta\beta$-decay to excited $0^{+}$ final states coming from the smaller kinematical factor $G_{01}$ [see Eq. (2.1)]. The values of $G_{01}$ are given in Table IV. One finds that the ratio $G_{01}(0_{g.s.}^{+})/G_{01}(0_{1}^{+})$ is about 12, 11, 5.2 and 21 for A=76, 82, 100 and 136 systems, respectively. By this factor
are the corresponding half-lifes to excited 0\(^+\) final state larger.

For a given nuclear isotope the characteristics of the 0\(\nu\beta\beta\)-decay refer both to the nuclear matrix element and the kinematical factor. For a chosen isotope, it is worthwhile to introduce sensitivity parameters with respect to different lepton number violating parameters. Large numerical values of these parameters may define those transitions and isotopes which are the most promising candidates for a lepton number violating signal, in the 0\(\nu\beta\beta\)-decay. These parameters are defined as follows [16,17]:

\[
\zeta_{<m_\nu>} (Y) = 10^7 |\mathcal{M}_{<m_\nu>}| \sqrt{G_{01} \text{ year}},
\]

\[
\zeta_{\eta_N} (Y) = 10^6 |\mathcal{M}_{\eta_N}| \sqrt{G_{01} \text{ year}},
\]

\[
\zeta_{\lambda_{111}} (Y) = 10^5 |\mathcal{M}_{\lambda_{111}}| \sqrt{G_{01} \text{ year}}. \quad (4.1)
\]

We listed the sensitivity parameters in Table IV. By a glance, one finds that within BEM the largest sensitivity parameters for the transitions to the 0\(^+\) state are associated with the A=100 system followed by the A=82 system. The smallest ones are of the A=76 and A=136 systems, i.e., these transitions are less favorable for an experimental study. Naturally, there are also additional aspects which experimentalists have to take into account in planning a search for the 0\(\nu\beta\beta\)-decay.

In Table IV, we present also theoretical half-lifes by assuming \(<m_\nu>=1\text{eV}, \eta_N=10^{-7}\) and \(\lambda_{111}=10^{-4}\). One finds that in order to get a limit on \(<m_\nu>\) of 1 eV, by measuring the transition to the excited 0\(^+_1\) final state, the experimentalists should reach the level of about \(10^{28}\) years for the half-life. By comparing the theoretical values of \(T_{1/2}^{0\nu}\) for the decay to ground state, with the predictions for the transition to the excited state 0\(^+_1\), both yielded by BEM, we note that the second ones are larger by about 1-2 orders of magnitude. This situation is shown also in Fig. 1. The question, for experimentalists, is whether the coincidence between the deexcitation \(\gamma\) and the emitted electrons allows to reduce the background in the 0\(\nu\beta\beta\)-decay experiment to a sufficient extent so that the constraints on lepton number violating parameters deduced from the transition to the 0\(^+\) excited state, can compete with those associated with transitions to the ground state. It might be that in the case of the 0\(\nu\beta\beta\)-
decay of $^{100}Mo$ to excited $0^+_1$ state triggered by light or heavy Majorana neutrino exchange mechanisms, the suppression of the half-life by a factor of 17 relative to the transition to ground state is compensated by diminishing the background events.

The expected improved experimental upper limits on the $0\nu\beta\beta$-decay half-life $T_{1/2}^{0\nu-exp}$, imply more stringent limits on lepton number violating parameters $<m_\nu>$, $\eta_N$ and $\lambda'_{111}$. By using the sensitivity parameters $\zeta's$ given in Table IV, they can be deduced in a straightforward way as follows:

$$<m_\nu> \frac{10^{-5}}{m_e} \leq \frac{10^{24} \text{ years}}{T_{1/2}^{0\nu-exp}}, \quad \eta_N \leq \frac{10^{-6}}{\zeta_{\eta_N}} \frac{10^{24} \text{ years}}{T_{1/2}^{0\nu-exp}},$$

$$(\lambda'_{111})^2 \leq \kappa^2 \left( \frac{m_{\tilde{q}}}{100 \text{ GeV}} \right)^4 \left( \frac{m_{\tilde{g}}}{100 \text{ GeV}} \right) 10^{-7} \sqrt{\frac{10^{24} \text{ years}}{T_{1/2}^{0\nu-exp}}},$$

with $\kappa = 1.8$ [4]. One finds that in order to push down the upper constraint on $<m_\nu>$ below 0.1 eV in the $0\nu\beta\beta$-decay experiment to excited $0^+_1$ final state, one has to measure the half-life of $4.02 \times 10^{28}$, $8.96 \times 10^{27}$, $7.59 \times 10^{26}$ and $4.77 \times 10^{28}$ years for A=76, 82, 100, 136 isotopes, respectively. Best present limits on this type of decay are on the level of $10^{21}$-$10^{22}$ years (see review [21]). But we would like to mention that some progress in measuring transitions to excited states is expected in the future. For example, experiment MAJORANA with 500 kg of $^{76}Ge$ plan to have sensitivity of $10^{28}$ years [15].

V. SUMMARY AND CONCLUSIONS

The $0\nu\beta\beta$-decay is a sensitive tool to study lepton number violating mechanisms, which are associated with the Majorana neutrino mass and R-parity violating supersymmetry. Neutrino oscillations indicate that we may be close to the observation of this exotic rare process. This stimulates both experimental and theoretical studies, which can be helpful to limit the effective Majorana neutrino mass $<m_\nu>$ below the 0.1 eV level. It is an open question whether the future $0\nu\beta\beta$-decay experiments measuring transitions to the excited final states can be of comparable sensitivity to different lepton number violating parameters as the ground to ground transitions. Experimental studies of transitions to an excited $0^+_1$
final state allows to reduce the background by gamma-electron coincidences. Drawbacks are lower Q values and possibly suppressed nuclear matrix elements. The theoretical studies of the corresponding nuclear transitions are of great interest.

We evaluated $0\nu\beta\beta$-decay nuclear matrix elements for transitions to first excited $0^+_1$ final states for $A=76, 82, 100$ and $136$ nuclei. The calculations have been performed within two known approaches, the boson expansion method (BEM) and recoupling two pairs of quasiparticle operators (RCM). The results of these two types of calculations differ from each other considerably especially in the case of exchange of heavy particles for $A=76, 82$ and $100$ systems. We indicated the drawbacks of the second approach. We also found anomalous behaviors of the RCM results for $A=136$ nuclei. The resulting matrix elements are summarized in Table I and Table II. The suppression of the decay matrix elements to $0^+_1$ in comparison with the decay to $0^+_g.s.$, depends on the isotope and $0\nu\beta\beta$-decay mechanism. An average suppression factor of about 2-3 is predicted by the BEM. Contrary to the RCM results, the BEM ones are significantly depending on the strength of the two-body interaction.

Further, we have calculated sensitivity parameters to different signals of lepton number violation associated with transitions to excited final states. We compared them with the ground to ground transitions. We have found the largest sensitivity to these parameters in the $A=100$ nuclear system. By comparing with the decay to $0^+_g.s.$ we find a suppression by a factor of about 4.1 for Majorana neutrino–exchange mechanisms. It means that the corresponding theoretical half-life is larger than that associated to the transition to $0^+_g.s.$, by factor of 17. In order to reach the sensitivity to a neutrino mass $< m_\nu >\approx 0.1$ eV in the $0\nu\beta\beta$-decay to an excited $0^+$ state, it is necessary to measure half-lifes of at least $8 \times 10^{26}$ years (as predicted by BEM). Perhaps, this limit might be expected to be reached by the $0\nu\beta\beta$-decay $^{100}Mo$ experiment in the near future.

This work was supported in part by the Polish-German Agreement on Science and Technology, grant no. 12N/99 and Pol98/050 and the State Committee for Scientific Researches (Poland), contract no. 2P03B00516. One of us, F.Š wants to thank the Department of
Theoretical Physics Maria Curie–Skłodowska University for their kind hospitality during his stay in Lublin and the Deutsche Forschungsgemeinschaft (436 SLK 17/298) for financing the stay in Tuebingen. A.R. wants to thank the International Buro Bonn (RUM-040-97) for supporting his stay in Tuebingen.
REFERENCES

TABLE I. Nuclear matrix elements of light and heavy Majorana neutrino exchange modes for the $0\nu\beta\beta$-decay in $A=76, 82, 100$ and $136$ nuclei. Both transitions to the ground state ($0^+_\text{g.s.}$) and the first $0^+_1$ excited states (which is assumed to be a two-phonon state) of the final nucleus are considered. The calculations have been performed within renormalized QRPA with the help of the recoupling (RCM) and the boson expansion (BEM) approaches for the evaluation of the one-body transition density. (f.s. means “final state” in the table).

FIG. 1. Calculated half-lifes of the $0\nu\beta\beta$-decay of $^{76}$Ge, $^{76}$Se, $^{100}$Mo and $^{136}$Xe for transitions to the ground $0^+_g$ and $0^+_1$ excited states of the final nuclei assuming $<m_\nu>_{ee} = 1\text{eV}$ (a), $\eta_N = 10^{-7}$ (b) and $\lambda_{111} = 10^{-4}$ (c). The black bars correspond to results describing ground state to ground state transitions as well as the results obtained for the transitions to the $0^+_1$ excited state within the boson expansion method (BEM). The open bars denote results obtained for transitions to the $0^+_1$ state via the recoupling method (RCM).
