Abstract

A summary of important LEP measurements in the $b$-quark physics is presented. The following topics are reviewed: $b$-fragmentation, the spectroscopy and lifetimes of beauty hadrons, $B^0 - \bar{B}^0$ oscillations and the extraction of the Cabibbo-Kobayashi-Maskawa (CKM) matrix elements $|V_{cb}|$ and $|V_{ub}|$.

1 Introduction

In the period 1989-1995 the LEP collider [1] was operated at center-of-mass energies around the $Z^0$ resonance (so called LEP I programme). Each of the four LEP experiments: ALEPH, DELPHI, L3 and OPAL [2], collected around 4.2 million of hadronic events. The fraction of these which are $b\bar{b}$ is high: $R_b = \Gamma_{b\bar{b}}/\Gamma_{had} \approx 22\%$. Moreover, contrary to 'B-factories' operating at the $\Upsilon(4S)$, at LEP there was sufficient energy to produce all $b$-hadrons, including $b$-baryons, $B^0_s$ and other hadrons with higher spin and orbital momentum.

Thanks to the relatively long lifetime of the beauty quark ($\tau \approx 1.5\,\text{ps}$), the $b\bar{b}$ events could be singled out by the presence of displaced secondary vertices, tracks with a significant impact parameter or a high rapidity, and a high transverse momentum of the leptons with respect to the jet axis ($p_T$). The typical purity (efficiency) of this so-called $b$-tagging was 60 (90)%, respectively ([3],[4]). This method, applied separately to both hemispheres, allowed to obtain accurate measurements of the relative width of the $Z^0$ into $b$-quarks were obtained. The combined result, $R_b = 0.21653 \pm 0.00069$ [5], corresponds to a precision of 0.3% and is in agreement with the expectation from the standard model.

The enriched $b\bar{b}$ samples allowed to perform many valuable tests of quantum chromodynamics (QCD). In particular, clear effects due to the $b$-quark mass running were observed. Comparing with the determinations at the $\Upsilon(4S)$ energies: $m_b(\Upsilon(4S)) \approx 4.2\text{GeV}$, the measurements of ALEPH [6] and DELPHI [7] of the running $b$-quark mass at the $Z^0$ pole yielded the average of $m_b(Z^0) = (2.96 \pm 0.36)\text{GeV}$. This value is consistent with the one predicted from QCD.

The $b$-tagging is also absolutely crucial for many other LEP studies, like the search for the Higgs boson, as discussed by C.Martinez-Rivero [8] at this conference.

2 $b$-fragmentation studies

The hadronization of beauty quarks into physical states can be studied by the measurement of the energy spectra of $b$-hadrons which are commonly described in terms of the fraction, $x_B = E_B/E_{beam} = 2E_B/\sqrt{s}$, of the beam energy retained by the weakly-decaying $b$-hadron ($E_B$ denotes the energy of beauty hadron and $\sqrt{s}$ is the center-of-mass energy). The predicted distribution of the energy of $b$-hadrons depends upon a convolution of perturbative QCD and the hadronization process itself. The nature of the latter is non-perturbative and is described by the phenomenological models.

The first studies at LEP ([9]-[12]) used the the momentum spectrum of the lepton from semileptonic decays of $b$-hadrons. They resulted in the mean value of $x_B$ of approximately 0.70. More recent analyses of ALEPH ([13],[14]) were based on semileptonic decays $B \rightarrow l\nu_l D^{(*)}(X)$\footnote{the charge-conjugate states are always implicitly considered}. The charmed mesons were reconstructed through the decay modes $D^{*+} \rightarrow D^0\pi^+$, $D^0 \rightarrow K^-\pi^+(\pi^0)$, $K^-\pi^+\pi^+\pi^-$, $K^0_s\pi^+\pi^-$, and $D^+ \rightarrow K^-\pi^+\pi^+$. The neutrino energy was estimated from the missing energy in the lepton hemisphere. The energy spectrum of $B$ mesons was obtained for approximately 3000 decays $B \rightarrow l\nu_l D^{(*)}(X)$. For the most recent measurement it yielded the value of $<x_B> = 0.7499 \pm 0.0065 \pm 0.0069$ [14] which points towards a harder $b$-fragmentation to compare with earlier studies. The SLD experiment [15] used a sample of 4200 inclusively reconstructed $B$ hadrons and yielded
< \langle x_B \rangle = 0.710 \pm 0.003 \pm 0.006. Both ALEPH and SLD, had compared the measured energy spectra with the predictions of different fragmentation models. The results are not fully consistent, but seem to favour the parametrizations of Kartvelishvili [16] and Peterson [17].

3 Spectroscopy and production rates of beauty hadrons

Before the LEP start-up, only the non-strange pseudoscalars $B^0_d$ and $B^+$ and vector meson $B^*$ were observed. The LEP studies confirmed the observation of the $B^*$, yielded evidence for the pseudoscalar, strange state $B_0^s$ and orbitally excited $B^{**}$, providing also hints for the presence of $B_{s}^{**}$ and radially excited states $B^{(*)}$. As far as the $b$-baryons are concerned, LEP confirmed unambiguously the existence of the $\Lambda_b$, observed the $\Xi_b$ and possibly the $\Omega_b$.

The experimental studies about the $b$-hadron spectroscopy were based on the inclusive reconstruction of beauty hadrons. Four-momenta of $b$-hadrons were reconstructed with the help of either a rapidity algorithm [18], or as a sum of four-momenta of tracks attributed to the secondary vertex [19]. In the rapidity approach, particles with rapidities above certain value, typically around 1.5, are considered to be the products of $b$-hadron’s decay. This allowed to reconstruct the four momenta of $b$-hadrons with an energy (angular) resolution of 7% (15mrad), respectively.

The mass of the $B^0_s$ meson was determined first from ALEPH [20], DELPHI [21] and OPAL [22] using six fully reconstructed decays to $D_s \pi$, $D_s a_1$ and $J/\psi \phi$. A bigger sample of $32 \pm 6$ decays $B^0_s \rightarrow J/\psi \phi$ was collected by the CDF [23]. The average mass [24] of the $B^0_s$ is $(5369.6 \pm 2.4)$MeV.

Using the samples of inclusively reconstructed $B$ hadrons, all four LEP collaborations ([18], [25]-[27]) had confirmed the first observations of the vector meson $B^*$, reported by CLEO [28] and CUSB [29]. As the mass splitting between the $B^*$ and $B$ is significantly smaller than the pion’s mass, only the electromagnetic decays $B^* \rightarrow B \gamma$ are allowed. At LEP, the photons were directly detected by L3. The other three experiments reconstructed $\gamma \rightarrow e^+ e^-$ conversions. The world average [24] of the $B^* - B$ hyperfine splitting (cf. Fig. 1 a) yielded: $\Delta M(B^* - B) = (45.78 \pm 0.25)$MeV. The $B^*$ and $B$ yields have been measured by all LEP collaborations ([18], [25]-[27]) and found to be consistent with the statistical spin composition: $\frac{\sigma_{B^*}}{\sigma_B + \sigma_{B^*}} = 0.748 \pm 0.004$.

The LEP experiments ([25], [30]-[32]) gave the first experimental evidence for orbitally excited $B^{**}$ mesons by combining single charged pions with $B$ mesons reconstructed inclusively. A broad maximum was observed in the spectrum of the $Q$-value of $B^{(*)} \pi$ pairs (cf. Fig. 1 b). In addition, ALEPH [33] had observed a similar resonant structure by using the sample of 404 fully reconstructed charged and neutral $B$ mesons. The shape of the maximum observed by this two approaches, was well described by the mixture of two broad and two narrow states, as expected by the Heavy Quark Effective Theory (HQET) [34]. However, the detailed decomposition into individual resonances is not possible yet. The world average [24] of the mass of the $B^{**}$ states is $(5697 \pm 9)$MeV and the production rate is $f_{B^{**}} = B(b \rightarrow B^{**} a_{u,d})/B(b \rightarrow B_{u,d}) = (30 \pm 10)%$.

Four events of fully reconstructed decays $\Lambda_b \rightarrow \Lambda_c \pi(a_1)$ were observed both by ALEPH [35] and DELPHI [36]. The most precise mass measurement of the $\Lambda_b$ was per-
Figure 1: The distribution of the mass difference $\Delta M(B^*-B)$ (plot A)) and $\Delta M(B^{**}-B)$ (plot B)) before (plots a) and after (plots b)) background subtraction. The data are represented by points with error bars. The curves on plots b) show the results of the fit using a Gaussian distribution for the signal.

formed by CDF [37]. The average mass of the $\Lambda_b$ is $m_{\Lambda_b} = (5624 \pm 9)$MeV. The $\Xi_b^-$ baryon was observed inclusively by ALEPH [38] and DELPHI [39] as an excess of same sign pairs $\Xi^- - \Lambda^-$ However, this partial reconstruction did not allow for the mass determination. The observation of the decays $\Sigma_b^{(*)} \rightarrow \Lambda_b \pi$ was reported only by DELPHI [40] and needs confirmation.

The production rates of pseudoscalar $b$-mesons and generic $b$-baryon were measured at LEP and CDF. The average results ([41],[42]) yielded:

$$f_{B_0^d} = f_{B^+} = (40.3 \pm 1.2)\%, \quad f_{B_0^s} = (9.4 \pm 2.2)\%, \quad f_{b-\text{baryon}} = (10.1 \pm 1.7)\%.$$ (1)

All results concerning the masses and production rates of beauty hadrons are in good agreement with the theoretical predictions, in particular with those given by HQET [34].

4 Lifetimes of beauty hadrons

The lifetimes of beauty hadrons depend on the magnitude of the CKM matrix elements $|V_{cb}|$ and on the dynamics of the decays of beauty hadrons. According to the spectator model, the lifetimes of all $b$-hadrons are equal. This prediction is modified after taking into account the effects resulting from the presence of the light quark (diquark) inside of beauty hadrons. In the framework of the Heavy Quark Expansion these effects can be estimated as an expansion in powers of $1/m_b$. It leads to the following predictions [43]:

$$\frac{\tau(B^+)}{\tau(B_0^d)} = 1 + 0.05 \times \left( \frac{f_B}{200\text{MeV}} \right)^2, \quad \frac{\tau(B_0^s)}{\tau(B_0^d)} = 1 \pm O(1\%), \quad \frac{\tau(\Lambda_b)}{\tau(B_0^d)} = (0.9 - 0.95)$$ (2)

where $f_B \approx 200\text{MeV}$ is the pseudoscalar decay constant. The LEP experiments, together with SLD and CDF, provided precise measurements of $b$-hadrons lifetimes which allowed to test quantitatively the relations given in Eq. 2.
The lifetimes of beauty hadrons were measured using four basic techniques. In the first, so-called ‘topological’ method, the $b$-decay vertices were reconstructed inclusively and the charge of the $b$-hadron was determined from the total charge of the tracks associated to vertex. This approach provided a large sample of events ($\sim 74000$ of $B^+$ and $B^0_d$) at the price of a reduced purity ($\approx 67\%$) and a substantial model dependence. The second, semileptonic technique exploited the partial reconstruction of semileptonic decays like $B^+ \to D^0 l^+ \nu l X$ and $B^0_d \to D^{(*)} l^+ \nu X$. High $p_T$ and $p_T$ leptons were identified and the charm hadron of the appropriate charge was partially or fully reconstructed. This method provided samples of a reasonably high statistics and purity (ALEPH [44]: 3700 events of $B^+$ and $B^0_d$, purity $\approx 85\%$). It required, however, the accurate determination of the missing four-momentum in order to estimate the four-momentum of neutrino. The third approach involved the full reconstruction of $b$-hadrons in hadronic decays. Their momenta were well determined, since there were no missing particles. Finally, some lifetime measurements were based on the impact parameters of tracks from the decays of beauty hadrons, in particular leptons.

The best measurements of $B^0_d$ and $B^+$ lifetimes were performed by LEP experiments and SLD using the topological and semileptonic methods. In the topological approach the purity of $B^0_d$ sample was limited by irreducible contamination of $B^0_s$ and $\Lambda_b$. The main source of systematic uncertainties in the semileptonic method was due to the presence of the physical background $B \to D^{**} l^+ \nu l$. For the $B^+$, the most accurate measurements were obtained by DELPHI [45], OPAL [46] and SLD [47], using the topological approach and by ALEPH [44] using $D^+ - l$ pairs. The average value of the $B^0_d$ lifetime is determined mostly by $D^+ - l$ measurements of ALEPH [44], DELPHI [48] and OPAL [49] and by topological results of DELPHI [45] and SLD [47]. The most accurate measurements of the $B^0_s$ lifetime were based on the study of $D_s - l$ pairs (ALEPH [50], CDF [51] and DELPHI [52]) coming from the decay $B^0_s \to D_s l^+ \nu l X$ and $D_s$ - hadron pairs (ALEPH [53] and DELPHI [54]) from $B^0_s \to D_s h X$.

The results concerning beauty baryons were commonly given as lifetimes of 'generic

\[
\begin{align*}
\tau_{B^0_d} &= (1.548 \pm 0.021) \text{ps} \\
\tau_{B^+} &= (1.647 \pm 0.021) \text{ps} \\
\tau_{B^0_s} &= (1.464 \pm 0.057) \text{ps} \\
\tau_{\Lambda_b} &= (1.208 \pm 0.051) \text{ps} \\
\tau_{\Xi_b^-} &= (1.229^{+0.081}_{-0.079}) \text{ps} \\
\tau_{\Xi_b^0} &= (1.39^{+0.34}_{-0.28}) \text{ps}
\end{align*}
\]
$b$-baryon’ and the $\Lambda_b$. In the first case the signal enrichment was obtained by the reconstruction of $\Lambda^0 - l$ (e.g. ALEPH [55], impact parameter technique) and $p - l$ (DELPHI [56]) pairs. The sample is composed mostly of the $\Lambda_b$, but the contribution for the $\Xi_b^-$, $\Omega_b$ etc. is not negligible ($\approx 15\%$). For $\Lambda_c - l$ pairs (ALEPH [55], DELPHI [56]) the $\Lambda_b$ lifetime is determined, as the yield of other $b$-baryons states can be safely neglected. One of the main sources of systematic uncertainties in the determination of $b$-baryon lifetimes comes from the $\Lambda_b$ polarization. The latter modifies the angular distributions of the $\Lambda_b$’s decay products. The polarization was measured using the average values of lepton and neutrino energies in the samples containing the $\Lambda^0 - l$ final state. The average of measurements from ALEPH [57], DELPHI [58] and OPAL [59] yielded $\mathcal{P}(\Lambda_b) = -0.45^{+0.17}_{-0.15} \pm 0.08$. ALEPH [38] and DELPHI [39] performed also the first measurements of the $\Xi_b^-$ lifetime using $\Xi^--l^-$ pairs. They were, however, of very limited statistical accuracy.

The average values of lifetimes of beauty hadrons, as given by the LEP $B$ Lifestyles Working Group ([42],[60]), are presented in Fig. 2. As far as $b$-mesons are concerned, the lifetime ratios are in good agreement with the theoretical expectations (cf. Eq. 2 and Fig. 2). The lifetimes of $b$-baryons and the $\Lambda_b$ are significantly smaller than expected. This discrepancy was discussed in numerous theoretical papers ([43],[61]). It may indicate a potential problem in the operator product expansion and the assumption of the quark-hadron duality. The experimental accuracy of the $\tau_{B_s^0}$ and $\tau_{B^+}$ will improve soon, on the basis of new results from the $B$-factories. The same is expected for the $B_s$ and $\Lambda_b$ from TEVATRON.

5 The branching fraction for semileptonic decays

$\mathcal{B}(b \rightarrow lX)$

Measurements of the branching fraction for semileptonic decays of beauty hadrons provide important information about the dynamics of heavy quark decays and allow to determine the size of the $|V_{tb}|$ CKM matrix element. The ‘direct’ $b \rightarrow l$ signal was separated experimentally from other components like the cascade $b \rightarrow c(\bar{c}) \rightarrow \bar{l}(l)$ and the $c \rightarrow \bar{l}$ transitions using the harder $p$ and $p_T$ distributions of the lepton from prompt $b$ decays. The decay topology, the charge correlation between the $b$-quark and the lepton and double $b$-tagged events where both $b$-hadrons decayed semileptonically ([62],[64]) were also exploited to suppress the backgrounds. The precision of all these methods was limited by the model dependence in the description of the signal and background spectra. The LEP average of the semileptonic branching fraction [65] yielded $\mathcal{B}(b \rightarrow lX) = (10.56 \pm 0.11 \pm 0.18)\%$ and was consistent with the value measured by the CLEO collaboration [66] as $\mathcal{B}(b \rightarrow lX) = (10.49 \pm 0.17 \pm 0.43)\%$. To account for the different beauty hadron species produced, the LEP results were rescaled by $1/(\tau_{B_s^0} + \tau_{B^+})/\tau_b$ where $\tau(b)$ denotes the average lifetime of beauty hadrons$^3$.

Once the total decay width is fixed, the yields of semileptonic, double charmed and charmless decays are correlated. Therefore it is appropriate to analyse the results concerning the $\mathcal{B}(b \rightarrow lX)$ in relation with the average number of charm hadrons in $B$ decays ($n_c$). The average of LEP measurements, $n_c = 1.171 \pm 0.040$, is consistent with the results of CLEO ($n_c = 1.159 \pm 0.049$) [65]. The measured values of $\mathcal{B}(b \rightarrow lX)$ and $n_c$ are

\begin{align*}
\tau_b &= f_{B_s^0} \cdot \tau_{B_s^0} + f_{B^+} \cdot \tau_{B^+} + f_{B_s^0} \cdot \tau_{B_s^0} + f_{b\text{-baryon}} \cdot \tau_{b\text{-baryon}}
\end{align*}
consistent with theoretical predictions.

6 Measurements of $|V_{cb}|$ and $|V_{ub}|$

The elements $|V_{cb}|$ and $|V_{ub}|$ of the CKM matrix are fundamental parameters of the standard model that can be determined in $b \to c l^- \bar{\nu}$ and $b \to u l^- \bar{\nu}$ decays. Experimentally, the semileptonic width is obtained from the average lifetime of $b$ hadrons and the semileptonic branching ratio:

$$\Gamma(B \to X_{c(u)} l \bar{\nu}_l) = \frac{BR(B \to X_{c(u)} l \bar{\nu}_l)}{\tau_b}$$

which leads to the following formulae for the $|V_{cb}|$ and $|V_{ub}|$:

$$|V_{cb}| = 0.0411 \sqrt{\frac{BR(b \to X_u l \bar{\nu}_l)}{0.105}} \sqrt{\frac{1.55 \text{ps}}{\tau_b \text{[ps]}}} \times (1 \pm 0.04)$$

$$|V_{ub}| = 0.00445 \sqrt{\frac{BR(b \to X_u l \bar{\nu}_l)}{0.002}} \sqrt{\frac{1.55 \text{ps}}{\tau_b \text{[ps]}}} \times (1 \pm 0.05).$$

This way of extraction of the $|V_{cb}|$ is commonly known as an inclusive method. In the so-called exclusive approach, the magnitude of the differential partial width of the decay $B_d^0 \to D^{*+} l^- \bar{\nu}$ as a function of $\omega$ i.e. the product of four-velocities of the $B$ and $D^*$ mesons:

$$\omega = v_B \cdot v_{D^*} = \frac{m_B^2 + m_{D^*}^2 - q^2}{2m_B m_{D^*}}, \quad q^2 = (p_B - p_{D^*})^2.$$  \hspace{1cm} (6)

The variable $\omega$ ranges from one in the point of zero recoil, when the $D^{*+}$ is produced at rest in the $B_d^0$ rest frame, to about 1.5. The differential decay rate is predicted to be

$$\frac{d\Gamma}{d\omega} = K(\omega) \cdot F_{D^*}(\omega) \cdot |V_{cb}|^2$$  \hspace{1cm} (7)

where $K(\omega)$ is a known phase-space function and $F_{D^*}(\omega)$ denotes the hadronic form-factor. In the heavy quark limit ($m_b \to \infty$), the form-factor coincides with the Isgur-Wise function and its magnitude at zero-recoil can be estimated using HQET [34] to be $F_{D^*}(\omega = 1) = 1$. This value is modified to $0.88 \pm 0.05$ [42] after taking into account the effects of a finite quark mass and QCD corrections. The Isgur-Wise form-factor is approximated with an expansion around $\omega = 1$ with the parameter $\rho$, interpreted as the slope of $F_{D^*}$ at zero recoil. As the phase space function vanishes in the limit of zero-recoil, the differential decay rate has to be measured close to $\omega = 1$ and extrapolated to determine the product $F_{D^*}(1) |V_{cb}|$.

The $D^{*+}$ mesons were observed in the decays to $D^0 \pi^+$. Due to the limited phase space available in this decay, the charged pion, denoted below as $\pi^*$, was produced almost at rest in the $D^*$ rest frame. The $D^0$ was reconstructed either exclusively, in particular decay modes $K^- \pi^+(\pi^0)$, $K^- \pi^+ \pi^- \pi^-$, and $K^0_s \pi^+ \pi^-$ (ALEPH [67] and OPAL [68]), or inclusively, by looking for generic secondary vertices consistent with the hypothesis of the $D^0$ decay, inside of the jet containing the lepton and the charged pion (DELPHI [69], OPAL [68]). The values of $F_{D^*}(1) |V_{cb}|$ and $\rho^2$ were extracted by a maximum likelihood fit to the
reconstructed \( \omega \) spectra (see Fig. 3). The fit took into account the combinatorial and the physics backgrounds. The first was estimated using events with wrong-sign \( \ell^- - \pi^+ \) charge correlation and from the mass sidebands. The latter was due to the presence of the decays \( B^0_d \rightarrow D^{**+}\ell^-\bar{\nu}_\ell \) where the \( D^{**+} \) decays to \( D^*\pi \) or \( D^*K \) and possibly also from non-resonant \( B^0_d \rightarrow D^{*+}\ell \bar{\nu}_\ell \) decays. The average of LEP results yielded

\[
\mathcal{F}_{D^*}(\omega) |V_{cb}| = 34.5 \pm 0.7 \pm 1.5 \times 10^{-3}
\]

\[
\hat{\rho}^2 = 1.01 \pm 0.08 \pm 0.16.
\]

The recent study of CLEO [70] gave somewhat higher value of \( \mathcal{F}_{D^*}(\omega) |V_{cb}| = 42.4 \pm 1.8 \pm 1.9 \times 10^{-3} \). Results for \( |V_{cb}| \), extracted by the LEP \( |V_{cb}| \) Working Group [71], using both inclusive and exclusive methods, are

\[
|V_{cb}|^{\text{inclusive}} = 40.7 \pm 0.5 \pm 2.0 \times 10^{-3}, \quad |V_{cb}|^{\text{exclusive}} = (39.8 \pm 1.8 \pm 2.2) \times 10^{-3}
\]

\[
|V_{cb}|^{\text{LEP average}} = (40.4 \pm 1.8) \times 10^{-3}.
\]

The magnitude of the \( |V_{ub}| \) was determined first by CLEO [72] and ARGUS [73] from the yield of leptons with momenta above the kinematical limit for \( b \rightarrow X_c\ell\bar{\nu}_\ell \) decays. In addition, the CLEO [74] collaboration measured the \( |V_{ub}| \) from the exclusive decays \( B \rightarrow \pi\ell\bar{\nu}_\ell \) and \( B \rightarrow \rho\ell\bar{\nu}_\ell \). The drawback of the first two approaches is their large model dependence. At LEP the extraction of the \( |V_{ub}| \) was recently performed by ALEPH [75], DELPHI [76] and L3 [77] from the study of properties of the hadronic system recoiling against the lepton. The main difficulty of this method was the isolation of the \( b \rightarrow u \) transitions from the dominant \( b \rightarrow c \), which yield was around 50 times bigger. The
Figure 4: Background subtracted energy spectrum of leptons $E_l^*$, measured in the $B$ meson rest frame, as obtained by the DELPHI for the $b \rightarrow u$ enriched (upper plot) and $b \rightarrow u$ depleted (lower plot) samples. The shaded histograms show the expected $E_l^*$ distribution for the signal of $b \rightarrow u$ semileptonic decays normalized to the fitted value of $|V_{ub}|/|V_{cb}|$.

discrimination between $b \rightarrow c$ and $b \rightarrow u$ is based on the differences in the invariant mass of the system accompanying the lepton, in kaon content and in the decay vertex topology and multiplicity.

The combination of LEP measurements yielded the value of the semileptonic branching ratio for the $b \rightarrow u$ transition of $BR(b \rightarrow X_u l^−\bar{\nu}_l) = (1.74 \pm 0.57) \times 10^{-3}$. Using the Eq. 5, this result can be translated into a value for the $|V_{ub}|$ provided by the LEP $|V_{ub}|$ Working Group:

$$|V_{ub}|^{\text{LEP average}} = (4.13^{+0.63}_{-0.75}) \times 10^{-3}$$

which is consistent with the recent CLEO determination [74]: $|V_{ub}|^{\text{CLEO}} = (3.25^{+0.61}_{-0.64}) \times 10^{-3}$. The systematic uncertainties associated with modelling $b \rightarrow u$ and $b \rightarrow c$ transitions are 10% (17%) for LEP (CLEO) results, respectively. They are, however, mostly uncorrelated.

7 $B^0 - \bar{B}^0$ oscillations

LEP did the first observation of time-dependent $B^0_d - \bar{B}^0_d$ oscillations (ALEPH [79]). The probability that a primary $B^0_{d(s)}$ has oscillated to a $\bar{B}^0_{d(s)}$ is given by:

$$\mathcal{P}(B^0_q \rightarrow B^0_q(\bar{B}^0_q))(t) = \frac{1}{2\tau_q} e^{-t/\tau_q} [1 \pm \cos(\Delta m_q t)]$$

where $\Delta m_{d(s)}$ is the mass splitting of the two mass eigenstates. The $B^0_s - \bar{B}^0_s$ oscillations are expected to be more than twenty times faster than those with $B^0_d - \bar{B}^0_d$.

To observe time-dependent $B^0 - \bar{B}^0$ oscillations both the production and decay flavour had to be tagged and the proper time must be accurately measured. For the $B^0_d - \bar{B}^0_d$ system, the $B$ flavour at the decay time can be tagged by the charge of the lepton, kaon
or $D^*$ meson attributed to the $B$ decay products or by the jet (hemisphere) charge. The latter is the momenta weighted charge of particles belonging to a jet (hemisphere). The $B$ flavour at the production time can be established either from the tracks belonging to the same hemisphere as the $B$ candidate (same-side tag) or the opposite hemisphere tracks (opposite-side tag) can be used. The basic same side tag is the charge of a track from the primary vertex. It is correlated with the production state of the $B$ if that track is the first particle in the fragmentation chain or a decay product of a $B^{**}$ meson. The charge of a lepton from $b \rightarrow l^-$ or of a kaon from $b \rightarrow c \rightarrow s$ or the hemisphere charge can be used as opposite-side tags. The oscillations were studied by performing a maximum likelihood fit to the distributions of fractions of events tagged as mixed and unmixed as a function of the proper time. Fig. 5 a) shows the $B_d^0$ oscillations. Here both the production and decay flavour were tagged by leptons. The like-sign di-leptons were a signature of an oscillation.

The 26 individual measurements of mass difference $\Delta m_d$ provided by LEP, SLD and CDF were averaged by the LEP $B$ Oscillations Working group([41],[42]) to be

$$\Delta m_d = (0.487 \pm 0.014) \, \text{ps}^{-1}.$$ 

Among the recent measurements, the most accurate was performed by OPAL [49]. It was based on inclusive reconstruction of $B_d^0 \rightarrow D^{*+}l^-\bar{\nu}_l$ decays. The $B_d^0$ decay vertex was reconstructed by intersecting the lepton with the soft pion from the decay $D^{*+} \rightarrow D^0\pi^*$. The flavour at the production (decay) time was tagged using the jet charge (lepton’s charge), respectively. The present average is dominated by LEP results. However, it is worthwhile to stress, that the preliminary results of $B_d^0 - \bar{B}_d^0$ oscillations obtained at $B$-factories [80] are not yet included.

Up to now, no experiment was able to show evidence for the fast $B_s^0 - \bar{B}_s^0$ oscillations. The experimental results are thus presented as lower limits of the oscillation frequency $\Delta m_s$. The $B_s^0$ oscillations were searched for using fully reconstructed decays, $D_s^-l^+$ final states and inclusive methods. Analyses of fully reconstructed $B_s^0$ have been performed in the channels $B_s^0 \rightarrow D_s^{(*)}\pi^+, D_s^{(*)}a_1^+, D^0K^-\pi^+$ and $D^0K^-a_1^+$ by ALEPH [81] and DELPHI [82]. The sample collected by DELPHI was composed of 44 decays with an estimated

Figure 5: a) Fraction of events in which the oscillation $B_d^0 - \bar{B}_d^0$ took place as a function of the reconstructed proper time; b) Combined measurements of the $B_s^0$ oscillation amplitude as a function of $\Delta m_s$. 

or $D^*$ meson attributed to the $B$ decay products or by the jet (hemisphere) charge. The latter is the momenta weighted charge of particles belonging to a jet (hemisphere). The $B$ flavour at the production time can be established either from the tracks belonging to the same hemisphere as the $B$ candidate (same-side tag) or the opposite hemisphere tracks (opposite-side tag) can be used. The basic same side tag is the charge of a track from the primary vertex. It is correlated with the production state of the $B$ if that track is the first particle in the fragmentation chain or a decay product of a $B^{**}$ meson. The charge of a lepton from $b \rightarrow l^-$ or of a kaon from $b \rightarrow c \rightarrow s$ or the hemisphere charge can be used as opposite-side tags. The oscillations were studied by performing a maximum likelihood fit to the distributions of fractions of events tagged as mixed and unmixed as a function of the proper time. Fig. 5 a) shows the $B_d^0$ oscillations. Here both the production and decay flavour were tagged by leptons. The like-sign di-leptons were a signature of an oscillation.

The 26 individual measurements of mass difference $\Delta m_d$ provided by LEP, SLD and CDF were averaged by the LEP $B$ Oscillations Working group([41],[42]) to be

$$\Delta m_d = (0.487 \pm 0.014) \, \text{ps}^{-1}.$$ 

Among the recent measurements, the most accurate was performed by OPAL [49]. It was based on inclusive reconstruction of $B_d^0 \rightarrow D^{*+}l^-\bar{\nu}_l$ decays. The $B_d^0$ decay vertex was reconstructed by intersecting the lepton with the soft pion from the decay $D^{*+} \rightarrow D^0\pi^*$. The flavour at the production (decay) time was tagged using the jet charge (lepton’s charge), respectively. The present average is dominated by LEP results. However, it is worthwhile to stress, that the preliminary results of $B_d^0 - \bar{B}_d^0$ oscillations obtained at $B$-factories [80] are not yet included.

Up to now, no experiment was able to show evidence for the fast $B_s^0 - \bar{B}_s^0$ oscillations. The experimental results are thus presented as lower limits of the oscillation frequency $\Delta m_s$. The $B_s^0$ oscillations were searched for using fully reconstructed decays, $D_s^-l^+$ final states and inclusive methods. Analyses of fully reconstructed $B_s^0$ have been performed in the channels $B_s^0 \rightarrow D_s^{(*)}\pi^+, D_s^{(*)}a_1^+, D^0K^-\pi^+$ and $D^0K^-a_1^+$ by ALEPH [81] and DELPHI [82]. The sample collected by DELPHI was composed of 44 decays with an estimated
$B_s^0$ purity of around 50%. Due to the excellent decay length resolution, this sample has a good sensitivity in the region of high $\Delta m_s$. Analyses of $D_s - l$ final states have a similar $B_s^0$ purity but worse proper time resolution. They lead to the samples of a few hundred events (ALEPH [81], DELPHI [52]). The highest sensitivity was achieved using the analyses of inclusive leptons. These studies provide around 50000 candidates with a $B_s^0$ purity of around 10% (ALEPH [83]). Moreover, the SLD collaboration [84] studied the $B_s^0 - \bar{B_s}^0$ oscillations using topologically reconstructed vertices of heavy quark decays.

To combine results of the different experiments and methods a specific amplitude method was put forward. The mixing probability, as given by formula 8, was modified by multiplying the oscillating term by the amplitude $A$. Thus, for each fixed value of $\Delta m_s$, the data were fitted to a function proportional to $1 + A \cos(\Delta m_s t)$. This corresponds to Fourier analysis of oscillation data with the amplitude studied as a function of the oscillation frequency. The oscillation amplitude was expected to be $A = 0$ ($A = 1$) for frequencies which are far from (close to), respectively, the true value of $\Delta m_s$. The measured oscillation amplitudes were combined [41], to provide the world average of amplitude spectrum presented in Fig. 5 b). A value of $\Delta m_s$ could be excluded at 95% C.L., corresponding to a value of the amplitude such that: $A + 1.645\sigma_A \leq 1$. The amplitude spectrum, combined from LEP, SLD and CDF measurements, excludes mixing for

$$\Delta m_s > 15.0 \text{ ps}^{-1} \quad \text{(LEP: } \Delta m_s > 11.8 \text{ ps}^{-1}).$$

The sensitivity, defined as the expected limit in $\Delta m_s$ at 95% C.L. corresponds to:

$$\Delta m_s^{\text{sens}} = 18.0 \text{ ps}^{-1} \quad \text{(LEP: } \Delta m_s^{\text{sens}} = 14.5 \text{ ps}^{-1}).$$

The amplitude spectrum exceeds value one in the range of oscillation frequencies between 15 and 20 ps$^{-1}$, reaching a maximum at $\Delta m_s = 17.8 \text{ ps}^{-1}$. This is interpreted as a hint of $B_s^0 - \bar{B_s}^0$ oscillations. The deviation of the measured amplitude from $A = 0$ is about 2.5 standard deviations. SLD and LEP experiments will provide improved limits on $\Delta m_s$ over this year. New results are also expected from CDF and, presumably D0, after the start of next run at TEVATRON in March 2001. Altogether it does not seem unlikely that a signal for $B_s^0$ oscillations at more than three standard deviations can be obtained. More detailed information about neutral $B$ mesons oscillation can be found in refs. [41], [42] and [85]- [87].

For the strange-beauty mesons, the width difference $\Delta \Gamma_s = \Gamma_s^H - \Gamma_s^L$ between the two mass and CP eigenstates$^4$ $B_s^L$ and $B_s^H$ is expected to be non-negligible reaching the value of around 20%. Experimentally the $\Delta m_s$ can be determined either by observing two different exponentials in the lifetime plots of $B_s^0$ or by measuring the lifetime of a CP eigenstate (e.g. $B_s^0 \rightarrow J/\psi \phi$) and comparing the estimated value with the average of the $\tau_{B_s}$. Assuming that $\tau_{B_s^d} = \tau_{B_s^0}$, the combination of results from LEP and CDF yielded $\Delta \Gamma_s / \Gamma_s = 0.16^{+0.08}_{-0.09}$ or $\Delta \Gamma_s / \Gamma_s < 0.31$ (95% C.L.) [42]. The results change to $\Delta \Gamma_s / \Gamma_s = 0.24^{+0.16}_{-0.12}$ or $\Delta \Gamma_s / \Gamma_s < 0.53$ (95% C.L.) if the assumption of equal $B_s^d$ and $B_s^0$ lifetimes is relaxed. These results are in qualitative agreement with theoretical expectations. However, they do not allow yet to draw a conclusion that the width difference $\Delta \Gamma_s$ is non-zero.

$^4$neglecting CP violation
Figure 6: Selected regions in the $\bar{\rho} - \bar{\eta}$ plane. The continuous curves represent the constraints resulting from the measurements of $|V_{ub}|/|V_{cb}|$, $\Delta m_d$, and $\epsilon_K$. The dotted curve corresponds to the 95% C.L. limit on the $\Delta m_s/\Delta m_d$. The bands surrounding the $|V_{ub}|/|V_{cb}|$, $\epsilon_K$ and $\Delta m_s/\Delta m_d$ curves represent the respective contours of 68% C.L. The allowed region (contour at 68% C.L.) is shown as a circle surrounding the region where the continuous and dotted lines cross.

8 Summary

The LEP measurements provided a dominant contribution in many domains of the $b$-quark physics. Among the major achievements are the determinations of lifetimes of individual $b$-hadrons which have been measured with an accuracy of (1.5–6)%; the results concerning the CKM matrix elements $|V_{cb}|$ and $|V_{ub}|$ and the measurement of the oscillation frequency for $B^0_d - \bar{B}^0_d$ mesons together with the stringent limit on $\Delta m_s$. Last but not least, LEP studied had improved significantly the knowledge of spectroscopic features of $b$-hadrons.

The LEP measurements of $|V_{cb}|$, $|V_{ub}|$, $\Delta m_d$ and $\Delta m_s$, together with constraints from the $\epsilon_K$ parameter, had large impact on the determination of the parameters of the unitary triangle (cf. Fig 6) leading to the values [86]:

$$\bar{\rho} = 0.206 \pm 0.043, \quad \bar{\eta} = 0.339 \pm 0.044, \quad \gamma = (58.5 \pm 6.9)^0$$

$$\sin 2\alpha = -0.28 \pm 0.27, \quad \sin 2\beta = 0.723 \pm 0.069.$$

Acknowledgements

I would like to express my gratitude to the organizers of the Conference for the invitation and a very pleasant atmosphere. The effort of all colleagues of the LEP collaborations is also gratefully acknowledged. Special thanks to P.Kluit and A.Stocchi for careful reading of the manuscript. This work was partially supported by the KBN grant 2 P03B 111 16 and SPUB-M/CERN/P-03/DZ 297/2000.
