Abstract. To address the important issue of how kinetic energy of collimated blast waves is converted into radiation, Pohl & Schlickeiser (2000) have recently investigated the relativistic two-stream instability of electromagnetic turbulence. They have shown that swept-up matter is quickly isotropized in the blast wave, which provides relativistic particles and, as a result, radiation. Here we present new calculations for the electrostatic instability in such systems. It is shown that the electrostatic instability is faster than the electromagnetic instability for highly relativistic beams. However, even after relaxation of the beam via the faster electrostatic turbulence, the beam is still unstable with respect to the electromagnetic waves, thus providing the isotropization required for efficient production of radiation. While the emission spectra in the model of Pohl and Schlickeiser have to be modified, the basic characteristics persist.

Key words. Instabilities – Plasmas – Turbulence – BL Lacertae objects: general

1. Introduction

Published models for the γ-ray emission of blazars are usually based on interactions of highly relativistic electrons of unspecified origin propagating in the relativistic jet of active galactic nuclei (Hartman et al. 1997, Bicknell et al. 2001, Catanese and Weekes 1999). The usual shock or stochastic electron acceleration processes would have to be very fast to compete efficiently with the strong radiative losses at high electron energies, which operate on timescales of the order of ten seconds for the rapidly variable γ-ray blazars, which is similar to the duration of a single shock crossing cycle for TeV electrons at a moderately relativistic shock assuming Bohm diffusion (Gallant & Achterberg 1998). Energetic electrons may also result as secondaries from photomeson production of highly relativistic hadrons, but the observed short variability timescale places extreme conditions on the magnetic field strength, for the hadron gyroradius has to be much smaller than the system size, and on the Doppler factor, for the intrinsic timescale for switching off the cascade is linked to the observed soft photon flux.

Here we consider the energisation of relativistic particles in jets by interactions with the surrounding medium. The rapid variability displayed in the γ-ray light curves of blazars requires the emission regions be less than ~0.01 pc in size. Also, VLBI observations of blazars indicate that the jets are not continuously filled emission regions, but consist of individual structures which relativistically move along a common trajectory and can be followed over years. On larger scales optical data still show individual knots, but also emission in-between (e.g. Boksenberg et al. 1992). Detailed spectral studies (e.g. Meisenheimer, Röser and Schlötelburg 1996) indicate that the spectrum of the synchrotron radiating electrons is fairly independent of position, suggesting that many acceleration sites with uniform characteristics are operational on scales of ~100 pc.

Accounting for these findings we model a jet as a channelled outflow with relativistic bulk velocity $V$, consisting of isolated plasma clouds or blast waves which contain cold electrons and protons of density $n_b$ (see Fig.1). These clouds may correspond to the individual components observed in VLBI images of blazars, whereas many of them and secondary electrons of escaped nucleons would contribute to the optical and X-ray jets observed on larger scales in nearby AGN such as M87. For convenience we assume that the outflow is directed parallel to the uniform background magnetic field. We also neglect a possible expansion of the jet cloud in this paper. Expansion is expected to occur on much longer timescales than the effects discussed here.

Each cloud of protons and electrons propagates into the surrounding interstellar medium that consists of cold protons and electrons of density $n_i^*$ (quantities indexed with an asterisk are measured in the laboratory (galaxy) frame). Viewed from the coordinate system comoving with the outflow, the interstellar protons and electrons represent a proton-electron...
beam propagating with relativistic speed $-V$ antiparallel to the uniform magnetic field direction. This situation is unstable and waves will be excited which backreact on the incoming beam. In our earlier analysis (Pohl & Schlickeiser 2000) the stability of this beam was examined under the assumption that the background magnetic field is uniform and directed parallel to the direction of motion. It was shown that the beam very quickly excitates low-frequency electromagnetic waves, which quasi-linearly isotopize the incoming interstellar electrons and protons in the blast wave plasma, thus providing relativistic particles. These processes are essentially those thought to operate in the first half-cycle of relativistic shock acceleration, but rather than assuming the existence of a hydrodynamical shock and a particular intensity of MHD turbulence, kinetic theory was used to self-consistently calculate the build-up of turbulence and its backreaction on the incoming interstellar particles.

The protons carry the bulk of the power, because velocities are conserved in the isotropization process and hence the protons have a factor of $\sim 2000$ more kinetic energy than the electrons. The protons produce high energy emission via the production of neutral pions in inelastic pp collisions. In parallel charged pions would provide secondary electrons which emit synchrotron radiation as well as bremsstrahlung and inverse Compton scattering. As discussed in Pohl & Schlickeiser (2000), the high energy emission produced by these particles has characteristics typical of BL Lacertae objects. The observed secular variability of the $\gamma$-ray emission of AGN would be related to the existence (or non-existence) of a relativistic blast wave in the sources, and thus to the availability of free energy in the system. The observed fast variability, on the other hand, would be caused by density inhomogeneities in the interstellar medium through which the blast wave propagates.

In parallel to the $\gamma$-rays, neutrinos are emitted whose spectrum and flux would be closely correlated with those of the $\gamma$-rays, which permits one to use the $\gamma$-ray light curves of blazars to very efficiently search for neutrino emission as a diagnostic for an hadronic origin of the high energy radiation (Schuster et al. 2001).

In the initial stage virtually no radio emission would be produced, for the plasma frequency and the synchrotron self-absorption frequency would be too high. After the initial $\gamma$-ray emission phase, when the blast wave has decelerated and expanded, a mm-radio flare would build up, which behaviour is preferentially observed in radio to $\gamma$-ray correlation studies of EGRET sources (Mücke et al. 1996).

Here we expand on the previous treatment by calculating the two-stream instability for longitudinal, electrostatic waves. In contrast to electromagnetic waves, which scatter the particles in pitch angle but preserve their kinetic energy until the distribution is isotropized, the electrostatic waves change the particles’ energy until a plateau distribution is established.

### 2. Longitudinal instabilities of a proton-electron beam

#### 2.1. The dispersion relation

For charge $e$, mass $m$ particles under the action of an electrical field $E = e_i E_\| \exp(ik(x - at))$, in the direction parallel to an ambient magnetic field the perturbations, $\delta f$, to the original distribution function satisfy

$$\frac{\partial \delta f}{\partial t} + v \frac{\partial \delta f}{\partial x} + eE \frac{\partial f}{\partial p} = 0$$

which, to first order in $\delta f / f_0$, and with $\delta f$ also taken to vary as $\delta f(p) \exp(ik(x - at))$ gives

$$ik(v_\| - a)\delta f + eE_\| \frac{\partial f_0}{\partial p_\|} = 0$$

i.e.,

$$\delta f = \frac{ieE_\|}{k(v_\| - a)} \frac{\partial f_0}{\partial p_\|}$$

The electrostatic balance equation requires

$$\text{div} E = 4\pi \sum e \int \delta f \, d^3p$$

where the sum is over charge species. Thus

$$k^2 E_\| = 4\pi \sum e^2 \int \frac{\partial f_0}{\partial p_\|} \, d^3p$$

Then the dispersion relation is

$$k^2 = 4\pi \sum e^2 \int \frac{\partial f_0}{v_\| - a} \, d^3p$$
Let $a = a_R + i a_I$. Then split the RHS of eq. 6 formally into the real part, $J$, and the imaginary part, $I$,

$$k^2 = J(a_R, a_I) + i I(a_R, a_I)$$

(7)

Because $k^2$ is meromorphic, then

$$I(a_R, a_I) = 0 \approx I(a_R, 0) + a_i \frac{\partial I(a_R, a_I)}{\partial a_i} |_{a_i=0}$$

(8)

The Cauchy condition yields

$$\frac{\partial I(a_R, a_I)}{\partial a_i} = \frac{\partial J(a_R, a_I)}{\partial a_R}$$

(9)

Thus the lowest order approximation yields

$$a_1 = - I(a_R, 0) \left( \frac{\partial J(a_R, 0)}{\partial a_R} \right)^{-1}$$

(10)

Then

$$J(a_R, 0) = 4\pi \sum e^2 P \int \frac{\delta f_0}{v_\parallel - a_R} d^3 p$$

(11)

where $P$ denotes the Cauchy principal value, while

$$I(a_R, 0) = 4\pi^2 \sum e^2 \int \frac{\delta f_0}{\delta p_\parallel} \delta(v_\parallel - a_R) d^3 p$$

(12)

Using the notation of Pohl & Schlickeiser (2000) the initial distribution function in the blast wave frame is (after correction of a typo in their Eq.3)

$$f(p, t = 0) = \frac{n_v \delta(p_\perp) \delta(p_\parallel + P) + n_v \delta(p_\perp) \delta(p_\parallel)}{2\pi p_\perp}$$

(13)

In this case Eq. 6 reduces to

$$k^2 = \Omega^2 \left[ \frac{1}{a^2} + \frac{\delta}{(a + V)^2} \right]$$

(14)

where $\Omega^2 = \omega^2_p + \omega^2_{p,e}$ and $\delta = n_i / (n_b \Gamma^3)$.

### 2.2. Properties of the dispersion relation

A plot of $k^2$ versus $a$ is given in Fig. 2. To be noted from the figure is that there are always two real values of $a$, occurring in $a > 0$ and $a < -V$, respectively. In the region $-V < a < 0$ the dispersion relation returns two real positive values of $a$, provided $k^2$ exceeds a minimum value, $k^2_{\text{min}}$, given by

$$k^2_{\text{min}} = \frac{\Omega^2}{V^2} (1 + \delta^{1/3})^3$$

(15)

occurring on

$$a_{\text{min}} = - V (1 + \delta^{1/3})^{-1} > -V$$

(16)

For values $k^2 < k^2_{\text{min}}$, the solutions are complex conjugate solutions in $-V \leq a_R \leq 0$. Note that on $k = 0$, the complex solutions are

$$a_0 = -V(1 + \delta)^{-1}(1 + i\sqrt{\delta}) = a_{\text{max}} (1 + i\sqrt{\delta})$$

(17)

Thus the range of $\phi$ is restricted to

$$\delta^{-1/6} \leq \tan \phi \leq \delta^{-1/2}$$

(18)

On $\tan \phi = \delta^{-1/6}$ note that $k^2 = k^2_{\text{min}}$ and $a_R = a_{\text{min}}$, and on $\tan \phi = \delta^{-1/2}$, $k = 0$ and $a_R = a_{\text{max}}$. Thus the range (21) covers the complete wavenumber spectrum where instability occurs. In Fig. 3 we show an enlargement of the dispersion relation in the phase velocity range where instability occurs. It is obvious that $k^2$ is basically independent of the phase velocity $a_R$, unless $a_R$ is very close to $a_{\text{max}}$. Therefore the Taylor expansion to first order (Eq. 10) is a poor approximation, for

$$\frac{\partial J(a_R, 0)}{\partial a_R} \approx 0.$$ 

A second order expansion would provide us only with $a_R^2$ which we have already derived in Eq. 20. However, Eq. 10 is very useful for determining the sign of the growth rate. Noting that $a_R < 0$, we see that $I(a_R, 0)$ is negative for negative $\frac{\partial J}{\partial a}$ because $\frac{\partial J}{\partial a} > 0$. $J(a_R, 0)$ is given in Eq. 14, provided $a$ is replaced by $a_R$. Obviously $\frac{\partial J(a_R, 0)}{\partial a_R} < 0$, and thus $a_1 < 0$. Since $k < 0$ we get for the growth rate

$$\gamma = ka_1 = |k| |a_1| > 0$$

(22)
Fig. 3. An enlargement of the dispersion relation for longitudinal waves in the phase velocity range where instability occurs. For small perturbation parameters, $\delta, k/k_{\text{min}}$ is essentially flat, unless $a_R$ is very close to $a_{\text{max}}$.

As in the non-relativistic case parallel electrostatic waves grow as long as the distribution function is inverted, whereas relativistic Landau damping would occur for $\frac{\partial f}{\partial p_{\parallel}} > 0$ with $p_{\parallel} < 0$.

The square of the growth rate is

$$\gamma^2 = k^2 V^2 y_t^2 = \Omega^2 \frac{(\sqrt{\delta} \tan^3 \phi - 1)(1 - \tan \phi \sqrt{\delta})}{(\tan^2 \phi - 1)^2}$$  \tag{23}

In Figs. 4 and 5 we show the growth rate as a function of the wavenumber $k$ and phase velocity, $a_R$, respectively. The growth rate is sharply peaked at wavenumbers close to $k_{\text{min}}$, but is essentially independent of the phase velocity, $a_R$.

2.3. Quasi-linear behavior

The time-dependent behavior of the intensities $I(k, t)$ of the excited waves is given by (Lerche 1967, Lee & Ip 1987)

$$\frac{\partial}{\partial t} I(k, t) = 2 \gamma I(k, t)$$  \tag{24}

Note that instability occurs only for negative wave phase speeds $a_R$, implying negative wavenumbers $k$.

To describe the long-term influence of the excited waves on the beam particles, which are the particles that can resonate with the waves, one uses the quasi-linear Fokker-Planck equation. Because the longitudinal waves act with an electric vector only, and because that vector parallels the magnetic field, the phase space density for the resonant particles then has only its momentum parallel to the ambient field influenced by the longitudinal turbulence. Hence, the corresponding Fokker-Planck equation reads

$$\frac{\partial f}{\partial t} = \frac{\partial}{\partial p_{\parallel}} \left( P \frac{\partial f}{\partial p_{\parallel}} \right)$$  \tag{25}
where the diffusion coefficient, \( D \), is given by

\[
D = \langle \Delta p_i^2 \rangle / \Delta t = 16 \pi^2 e^2 \int_{k_{\text{min}}}^{k_{\text{max}}} dk \frac{\delta [k (v_i - a_R)]}{|k|}
\]

(26)

The corresponding diffusion equation for each resonant particle species is

\[
\frac{\partial f}{\partial t} = 16 \pi^2 e^2 \frac{\partial}{\partial p_i} \left( \int_{k_{\text{min}}}^{k_{\text{max}}} dk \frac{I(k)}{|k|} \delta (v_i - a_R) \frac{\partial f}{\partial p_i} \right)
\]

(27)

where \( a_R \) is related to the wavenumber \( k \) through equation (19).

Note that some care has to be exercised in treating the \( \delta \)-function in equation (27) for two reasons. First, slight variations in the phase velocity, \( I(a_R) = I(k) k_{\text{min}} \), is flat between \( a_{\text{min}} \) and \( a_{\text{max}} \) zero outside this range (Akhiezer et al. 1975). Upon interaction with this wave spectrum the beam will relax to a plateau between the velocities \( -V \) and \( v_i = a_{\text{min}} \). The energy available for the build-up of the waves comes from the beam. Because the wave growth is much faster than the relaxation of the beam, we may estimate the final wave intensity spectrum as the ratio of the energy lost by the beam during relaxation to a plateau between the velocities \( -V \) and \( v_i = a_{\text{min}} \) and the phase velocity range in which effective growth occurs, namely \( \delta V / 3 \). Therefore we may write

\[
\Delta E \simeq \frac{n_i}{2} m_p c^2 \Gamma^3 \delta V / 3
\]

(30)

\[
\Delta a_R \simeq V \delta V / 3
\]

(31)

\[
I(a_R) \simeq \frac{\Delta E}{\Delta a_R} \simeq \frac{n_i}{2} m_p c^2 \Gamma^3 = I_0
\]

(32)

where we keep in mind that \( a_R \) is to be taken between \( a_{\text{min}} \) and \( a_{\text{max}} \). The diffusion coefficient is then

\[
D(p_i) = 16 \pi^2 e^2 I_0 \int_{a_{\text{min}}}^{a_{\text{max}}} da_R \frac{1}{|k|} \delta (v_i - a_R) = 16 \pi^2 e^2 \frac{I_0}{|k(a_R = v_i)|} \simeq 2 \pi m_e m_p c^2 \Gamma^3 \Omega n_i / n_b
\]

(33)

where we have used again that \( k \simeq k_{\text{min}} \simeq -V / \Omega \) in the resonant range. The time scale for the relaxation of the beam by the electrostatic instability can then be estimated as

\[
\tau \simeq \frac{P^2}{D} \simeq \frac{m_p n_b}{2 \pi m_e n_b \Gamma} \simeq 5 \cdot 10^{-3} \frac{\sqrt{n_i}}{\Gamma n_i} \text{ sec}
\]

(34)

In terms of the interstellar matter density in the laboratory frame, \( n_i^* \), and the scaled variables \( n_s = 10^{-8} n_b \) and \( \Gamma = 10^{-2} \Gamma \) the relaxation time scale reads

\[
\tau = 5 \cdot 10^{-3} \sqrt{n_s} \Gamma^2 / n_i^* \text{ sec}
\]

(35)
which is two orders of magnitude shorter than the time scale for the electromagnetic instability derived in Pohl & Schlickeiser (2000).

2.5. Highly variable transverse speed

Suppose the initial beam is slightly dispersed, such that all particles have the same total momentum, \( P \), but instead of flying exactly backwards (\( \mu = -1 \)) the particles homogeneously occupy a fixed solid angle element defined by \( \mu \leq \mu_c \). This initial condition approximates the situation after the onset of pitch angle scattering but long before the isotropization is completed. The initial distribution function in the blast wave frame is then

\[
f(\mathbf{p}, t = 0) = \frac{n_0 \delta(p_\perp) \delta(p_\parallel)}{2\pi p_\perp} + \frac{n_0 \delta(\sqrt{p_\perp^2 + p_\parallel^2} - P) \Theta(\mu_c - \frac{p_\parallel}{P})}{2\pi P^2 (1 + \mu_c)}
\]  
\[
(36)
\]

The dispersion relation \( \beta \)

\[
k^2 = \Omega^2 \left[ \frac{1}{a^2} + \frac{\delta \Gamma^2}{c^2 (1 + \mu_c)} \int_{-1}^{1} dy \beta^{-2} - y^2 \right]
\]  
\[
(37)
\]

where \( \beta = V/c, y = p_\parallel/P, \) and \( \delta = n_1/(n_0 \Gamma^3) \) as in Eq.(17). The integral in Eq.(37) can be trivially solved and we obtain the dispersion relation for a dispersed beam with \( x = a/V \) and \( \epsilon = 1 + \mu_c \)

\[
\frac{k^2 V^2}{\Omega^2} = \frac{1}{a^2} + \delta \Gamma^2 g(x)
\]  
\[
(38)
\]

with

\[
g(x) = \frac{1}{\epsilon} \int_{-1}^{1} dy \frac{\beta^{-2} - y^2}{(y - \frac{a}{c})^2}
\]

which for \( \epsilon \to 0 \) would reduce to Eq. 14. For small \( \epsilon \) we can derive modifications

\[
x = x_0 + x_1
\]  
\[
(39)
\]

to the cold beam solutions \( x_0 \) (Eq.18) of the dispersion relation by expanding the right-hand-side of Eq.38, \( \text{RHS}(x, \epsilon) \).

\[
\frac{k^2 V^2}{\Omega^2} = \epsilon \frac{\partial \text{RHS}(x_0, \epsilon)}{\partial \epsilon} \bigg|_{\epsilon=0} + x_1 \frac{\partial \text{RHS}(x_0, \epsilon)}{\partial x} \bigg|_{x=x_0}
\]

\[
+ \frac{x_1^2}{2} \frac{\partial^2 \text{RHS}(x_0, \epsilon)}{\partial x^2} \bigg|_{x=x_0} + \text{RHS}(x_0, 0)
\]  
\[
(40)
\]

The second order expansion in \( x \) is necessary because the first order term in \( x \) is zero for \( \tan \phi = \delta^{-1/6} \).

The term \( \text{RHS}(x_0, 0) \) is identical to the right-hand-side of the dispersion relation for an ideal beam (14), and hence equal to \( k^2 V^2/\Omega^2 \). The remaining binomial expression in \( x_1 \) is solved by

\[
x_1 = (1 + x_0) \left[ (1 + x_0^{-1})^3 + \delta - \sqrt{f(x_0, \epsilon)} \right] / 3 \left[ (1 + x_0^{-1})^4 + \delta \right]
\]  
\[
(41)
\]

Fig. 6. The normalized phase velocity modification, \( \Re x_1 \), for different beam openings, \( \epsilon \), and different bulk Lorentz factors, \( \Gamma \). The perturbation parameter \( \delta \) is held constant. The phase velocity modification scales approximately linearly with \( \epsilon \), unless \( \alpha_R \) is close to \( a_{\text{min}} \).

Fig. 7. The growth rate modification, \( \gamma_1 \), as a function of the unmodified phase velocity \( a_R \) for different beam openings, \( \epsilon \), and different bulk Lorentz factors, \( \Gamma \). The perturbation parameter \( \delta \) is held constant. The growth rate modification has a similar dependence on the parameters as has the phase velocity modification.

where

\[
f(x_0, \epsilon) = \left[ (1 + x_0^{-1})^3 + \delta \right]^2 - 3\epsilon \Gamma^2 \frac{1 + \beta^2 x_0}{1 + x_0} \left[ (1 + x_0^{-1})^4 + \delta \right]
\]  
\[
(42)
\]
Here we have also used
\[
\lim_{\epsilon \to 0} x_1 = 0
\]
(43)
to resolve the ambiguity in sign.

For the expansion we require
\[
\frac{\epsilon}{1 + x} \ll 1
\]
(44)
which leads to a limit for the opening half-angle of the beam
\[
\cos^{-1} \frac{1}{2} \phi = \frac{\delta}{\epsilon} \tan^{-1} \frac{1}{2} \quad \text{for} \quad \tan \phi = \delta^{1/2}
\]
(45)

The limiting opening half-angle is about 10 arcminutes for \( \delta = 10^{-10} \). For all \( \epsilon \) satisfying Eq.45 the parallel velocities \( v_{||} \) are always larger than the phase velocities in the range where instability occurs.

In Fig.6 we show the phase velocity modification, \( V R x_1 \), for different parameters. The phase velocity modification scales approximately linearly with \( \epsilon \), unless \( a_R \) is close to \( a_{\min} \), which reflects the dominance of the first order term in \( x_1 \) over the second order term in Eq.40 for all \( a_R \) not too close to \( a_{\min} \). Fig.7 shows the growth rate modification, \( \gamma_1 \), for different parameters.

In Fig.8 we show the modified growth rate, \( \gamma + \gamma_1 \), as a function of the modified phase velocity, \( a_R + V R x_1 \). To be noted from the figure are

- The growth rate increases if the beam has a finite opening angle.

\[ \gamma \] is the limiting beam opening half-angle is about 10 arcminutes, unless \( a_{\min} \) is close to \( a_R \), for all \( a_R \) not too close to \( a_{\min} \). Fig.7 shows the growth rate modification, \( \gamma_1 \), for different parameters.

In Fig.8 we show the modified growth rate, \( \gamma + \gamma_1 \), as a function of the modified phase velocity, \( a_R + V R x_1 \). To be noted from the figure are

- The growth rate increases if the beam has a finite opening angle.

3. Discussion

We have calculated the excitation of longitudinal, electrostatic turbulence subsequent upon the injection of a relativistic electron-proton beam into a cold background plasma. In contrast to electromagnetic waves, which scatter the particles in pitch angle but preserve their kinetic energy until the distribution is isotropized, the electrostatic waves change the particles’ energy until a plateau distribution is established. Our results can be applied to models of AGN and GRB, which are based on a relativistic blast waves traversing the ambient medium.

As one example of such models, two of us have recently published a calculation of an electromagnetic two-stream instability in a channeled relativistic outflow, a jet, and shown that the isotropization of the incoming interstellar particles would provide relativistic particles in the AGN, the electrostatic instability is much faster than the electromagnetic instability, even in case of a weak dispersion of the incoming beam. The beam will therefore relax to a plateau-distribution in \( p_{||} \), which, however, is still unstable with respect to electromagnetic waves. The spectrum of electromagnetic waves excited by a plateau-distribution in \( p_{||} \) will not be a \( k^{-2} \) spectrum as in the case of a cold beam, for it can be understood as a superposition of the wave spectra produced by cold beams with different energies, each of which would be a \( k^{-2} \) spectrum with energy-dependent upper and lower limits in \( k \). Nevertheless, isotropization in the collimated blast wave would still occur on roughly the same time scale as calculated by Pohl & Schlickeiser (2000).

Therefore, the main effect of the electrostatic instability is a change in the spectrum of swept-up particles. Instead of the prior result for the differential sweep-up rate in the absence of the electrostatic instability

\[
\dot{N}(\gamma)_{\text{no e.s.i.}} = N_0 \delta (\gamma - \Gamma)
\]

(46)
we now obtain

\[
\dot{N}(\gamma)_{\text{e.s.i.}} = \frac{N_0}{\Gamma - 1} \Theta (\Gamma - \gamma)
\]

(47)

In the radiation spectra this change corresponds to a reduction of efficiency by roughly 50% at the highest energies and little change at smaller energies, because in the inelastic pp collisions the pion source power scales roughly with the kinetic energy of the incident proton, hence the pion spectra are dominated by the pions produced by the protons of high energy for flat proton spectra. In Fig.9 we show the spectra of \( \pi^0 \) decay \( \gamma \)-rays for the case of a fast electrostatic instability (Eq.47) in comparison with the case of the electromagnetic instability only (Eq.46). At photon energies well below the peak energy of the \( \nu F_\nu \) spectra the difference in spectral index is
only $\Delta s \simeq 0.1$. Similarly, small changes can be expected for the injection spectra of secondary electrons and hence for the synchrotron spectra at optical to X-ray frequencies. Therefore the isotropization and radiation conclusions drawn by Pohl & Schlickeiser (2000) are still valid. About half of the energy flux carried by the incoming beam is channeled into electrostatic turbulence. It is instructive to calculate the group velocity of the waves with which the wave energy is transported. In Fig. 10 we show the group velocity for the initial ideal beam (Eq.19) in the phase velocity range where instability occurs. The group velocity is fairly independent of the weighted beam intensity, $\delta$, and it is always larger than $0.5 \, V \simeq 0.5 \, c$. Therefore, the energy carried by the electrostatic waves is rapidly transported toward the backside of the blast wave. Because the waves carry 50% of the energy flux of the incoming beam with a transport velocity of 50%–100% of the beam velocity, the energy densities in the final wave field and the initial beam should be similar.

$U_W = \int da_R \, I(a_R) \simeq n_i \, m_p c^2 \, \Gamma = n_i^* \, m_p c^2 \, \Gamma^2$  \hspace{1cm} (48)

The high energy density of waves has two important aspects, which are briefly discussed in the following sections.

### 3.1. Nonlinear evolution of the wave field

Quasi-linear theory is not valid under all physical conditions. When the energy density of the wave field is not small, nonlinear effects may become important.

One important effect is nonlinear Landau damping (Sagdeev & Galeev 1969). This is the interaction between thermal particles and the beat of two electrostatic waves: if the phase velocity of the beat wave is almost equal to the thermal velocity of charged particles in the background plasma, the particles would Landau-damp the beat wave and hence be heated. If the remaining wave has a superluminal phase velocity, it will not resonate with the beam particles anymore. As a consequence, the number of scattering processes between the beam particles and the waves, which are responsible for the production of a plateau in the beam distribution function, would be drastically reduced. This process reduces the wave intensity in the resonant phase velocity range as long as the intensity of waves with superluminal phase velocity is not so strong that nonlinear interactions in this regime cause wave energy to be retransferred to resonant subluminal phase velocities.

The nonlinear Landau damping is a process resulting from weak turbulence theory: although waves interact, the wave energy is small enough that individual waves are identifiable. If the wave energy is too high, strong turbulence theory applies (Zakharov 1972). The charge distribution in the background plasma, which results from the electric field of the waves (essentially the RHS of Eq.4), becomes so strong that it affects the dispersion relation. As a result, the wave field will collapse into cavitons (Goldman 1984) in which the plasma has a low density. This effect will depend on the temperature of the background plasma, and on whether or not the diffusive particle motion can effectively smear out the depleted cavitons, and thus impede their build-up.

Without having performed a detailed study of these effects in a background medium with possibly time-variable temperature caused by heating processes, we can only speculate on the impact of the nonlinear effects, which would increase the time scale for the plateau production of the beam (Eq.35). However, because that time scale is more than two orders of magnitude...
shorter than the time scale for the electromagnetic instability, even if important such nonlinear effects would likely still permit the production of a plateau on a timescale much faster than the isotropization.

3.2. Where does the wave energy go?

Part of the wave energy will be transferred to the background plasma in the blast wave. We have already discussed the nonlinear Landau damping, in which thermal particles would absorb the beat of two electrostatic waves. But, in the general case, the natural width of the resonance Lorentz profile combined with the Maxwellian distribution function allows thermal particles to Landau damp the waves with $v_\phi \simeq c$, albeit with a small probability.

We do not know the fraction of the wave energy density that is channeled into heating processes of the blast wave plasma. Here we concentrate on a qualitative discussion of the possible effects.

The wave energy is transported quickly toward the backside of the collimated blast wave. At the transition between the blast wave and its wake, the dispersive properties of the blast wave change. We can, therefore, expect that a part of the wave field is reflected at the backside, and possibly again reflected at the front side and so forth. If the reflection coefficient is not small, the wave energy density inside the blast wave would increased, until nonlinear effects at the front and backside cause the waves to escape. The heating rate would be similarly enhanced.

What would be the effect of strong heating in the blast wave? As an extreme example consider that the full wave energy flux is available for homogeneously heating the blast wave. The heating rate then is

$$\dot{T} \approx \frac{(\gamma - 1)n_i^4 m_p c^3 \Gamma^2}{2n_b d k} \approx 10^6 \frac{n_i^4 \Gamma^2}{n_b d_{13}} \text{ K/sec}$$

(49)

where we have used the scaled variables $n_8 = 10^{-8} n_b$, $d_{13} = 10^{-13} d$, and $\Gamma_2 = 10^{-2} \Gamma$. This heating rate would be too large to be balanced by any cooling process of a non-relativistic plasma. Therefore run-away heating would occur until non-thermal cooling processes set in at semi-relativistic energies.

The existence of radio galaxies implies that the collimation of AGN jets is well maintained on linear scales of hundreds of kiloparsecs. A semi-relativistic plasma jet could hardly remain collimated on these scales, because the expansion by internal pressure alone would cause a substantial opening of the jet. We may take the observed collimation of jets in radio galaxies as empirical evidence against excessive heating. For the fate of the electrostatic wave field, this observation indicates that the reflection efficiency of waves at the backside of the blast wave is small, whatever the cause.

Since the waves carry momentum, even a small reflection would transfer momentum to the background plasma at the backside of the blast wave, which would then "boil off" the blast wave and fill its wake. The waves that have escaped the blast wave would fill the wake and the regions around it, and be finally damped by the interstellar plasma in the host galaxy of the AGN, thus giving rise to additional heating of the interstellar medium around the AGN jet.
