Abstract

Modern far infrared and submillimeter instruments require large format arrays. We consider the relative performance of filled array (bare pixel) and feedhorn-coupled architectures for bolometer focal planes. Based on typical array parameters, we quantify the relative observing speeds and comment on the merits of the different architectures. Filled arrays can provide higher mapping speed (by a factor of up to 3.6) and simpler observing modes at the expense of reduced sensitivity for pointed observations, increased detector numbers, and greater vulnerability to stray light and electromagnetic interference. Taking advantage of the filled array architecture requires strongly background limited detectors. At millimeter wavelengths, filled arrays must be surrounded by a sufficiently cold enclosure to minimize the background power from the instrument itself.
1. Introduction

Imaging bolometer instruments in the submillimeter spectral region ($\lambda > 200 \, \mu m$) are needed for a variety of important astrophysical studies including star formation, galaxy formation and evolution, active galactic nuclei, evolved stars, comets and asteroids. To date, most bolometer camera instruments have used composite semiconductor bolometers mounted in individual integrating cavities and coupled to the telescope by means of single-mode or few-moded feedhorns. New bolometer instruments are now being built or planned to provide improved sensitivity and field of view. An alternative focal plane array architecture involves dispensing with feedhorns and filling the focal plane with an array of bare bolometers. In this paper we consider the advantages and disadvantages of these alternative array architectures and calculate their relative observing speed for pointed and mapping observations, based on reasonable assumptions and typical array parameters. The speed improvements achievable in principle (for the completely background-limited case) are calculated, and the effect of finite detector NEP on mapping speed is also considered. The feedhorn and filled array architectures, and the assumptions made for the purposes of inter-comparison, are described in Section 2. The main performance parameters of the different options are presented in Section 3. In Section 4 we derive expressions for the relative observing speed of the different options, and the results of calculations are presented and discussed in Section 5.

The definitions of the symbols used in this paper are given below.

$A_T$   Telescope area

$A\Omega$ Throughput (area-solid angle product) with which the detectors receive incident radiation
\( B_\nu(T) \)  Planck function

\( B_{\text{ext}} \)  Overall surface brightness viewed by the detectors coming from outside the instrument

\( B_{\text{int}} \)  Overall surface brightness viewed by the detectors coming from the cold box surrounding the detectors

\( D \)  Telescope primary aperture diameter

\( F \)  Focal ratio of the instrument final optics feeding the detectors

\( \text{NEP}_{\text{det}} \)  Detector \( \text{NEP} \)

\( \text{NEP}_{\text{ph}} \)  Photon noise limited \( \text{NEP} \) referred to the background radiant power absorbed by the detector

\( P_{A,C,S,T} \)  Power absorbed by a detector from the atmosphere, instrument cold box, astronomical sky, and telescope, respectively

\( P_{\text{tot}} \)  Total radiant power absorbed by a detector

\( R \)  The ratio of the internal (cold box) to external surface brightness: \( B_{\text{int}} / B_{\text{ext}} \)

\( S_\nu \)  Point source flux density at the telescope aperture

\( T_{A,C,S,T} \)  Atmospheric temperature, detector cold box temperature, astronomical sky brightness temperature, and telescope temperature, respectively

\( \alpha \)  Fraction of the detector throughput which illuminates the telescope. A fraction \( 1 - \alpha \) is assumed to terminate on the inside of the detector cold box.

\( \beta \)  Ratio of number of detectors in the array to the number for an array of \( 2F\lambda \) feedhorn pixels with the same total area
\( \gamma \)  
Ratio of detector NEP to photon noise NEP (i.e., \( \frac{NEP_{\text{det}}}{NEP_{\text{ph}}} \))

\( \sigma \)  
Signal-to-noise ratio for a given detector or map point

\( \Delta \theta \)  
Angular offset of the telescope pointing from a point source

\( \varepsilon_\lambda \)  
Atmospheric emissivity

\( \varepsilon_t \)  
Telescope emissivity

\( \lambda, \nu \)  
Central wavelength, frequency of band-pass filter

\( \Delta \lambda, \Delta \nu \)  
Filter bandwidth (the filter is assumed to have a top-hat transmission profile)

\( \eta_d \)  
Detector responsive quantum efficiency

\( \eta_o \)  
Instrument overall transmission efficiency

\( \eta_{\text{pix}} \)  
Fraction of the total power from a point source diffraction pattern that is coupled to a detector centered on the source

\( \theta_{\text{FWHM}} \)  
Full-width-half-maximum beam width on the sky

\( \tau \)  
Integration time per detector

2. **Array architectures**

2.1 **Feedhorn arrays**

Most submillimeter bolometer cameras to date have used feedhorn arrays with NTD germanium composite bolometers [e.g., Refs. 1, 2, 3, 4]. Feedhorn arrays will also be used for the Herschel-SPIRE \(^5\) and Planck-HFI \(^6\) satellite instruments.
Circular-aperture feedhorns are usually close-packed in the focal plane to fit as many detectors as possible into the available area. Corrugated horns provide a near Gaussian antenna pattern. Smooth-walled conical horns have higher side-lobes due to the sharp transition in the fields at the outer edge of the horn aperture, but are simpler and cheaper to manufacture in large numbers. The feedhorn restricts the detector field of view, giving a tapered illumination of the telescope primary mirror, with an edge taper of typically 8-12 dB for $2F\lambda$ horns. The main beam profile on the sky is a good approximation to a Gaussian, whose width depends on the edge taper. Observing modes with feedhorn arrays must take into account the fact that although the horns are close-packed in the focal plane, their beams on the sky do not fully sample the image unless the horn diameter is $0.5F\lambda$ or less. Several separate telescope pointings are therefore needed to create a fully-sampled image. For $2F\lambda$ horns, at least 16 pointings are required, as illustrated in Figure 2. For horns of $1F\lambda$ aperture, 4 pointings are required. Full sampling is achieved by moving ("jiggling") the array pointing. Alternatively, a fully sampled image of a large area can be obtained by scanning the array across the sky at the appropriate angle to provide the necessary overlap between beams.

The main advantages of $2F\lambda$ feedhorn arrays are:

(i) a $2F\lambda$ feedhorn provides maximum efficiency for detection of a point source with known position (because most of the power from the source is concentrated on a single detector);
(ii) horn properties are well-understood, allowing good control of the beam and reliable design;
(iii) the bolometer field of view is restricted to the telescope, giving good stray light rejection;
(iv) the susceptibility to electromagnetic interference can be controlled - the horn plus integrating cavity act as a Faraday enclosure;
(v) Feedhorn arrays allow for the minimum number of detectors for a given total field size.

The main disadvantages are the need for jiggling or scanning, which complicates the observing modes, and, more importantly, that the efficiency for mapping is considerably less than the ideal value. The feedhorn acts as a directional antenna, restricting the field of view of the detector to the telescope. The interferometric nature of any antenna means that an inevitable price is paid for this directivity in that some of the power incident on the horn array is actually reflected back out.

2.2 Filled arrays

Filled detector arrays dispense with feedhorn or antenna coupling of the detectors to the incoming beam in favor of an array of rectangular (usually square) absorbing pixels. To achieve instantaneous full sampling of the image, the pixel center-to-center spacing must be $0.5F\lambda$ or less. The broad field of view of each individual pixel ($\sim \pi$ sr), requires the use of a cold stop in the optical system, and gives a flatter illumination profile for the telescope. This is advantageous if the application requires maximum point source sensitivity, but not if high side-lobe suppression is needed (this configuration might not be optimal for cosmic background observations, for instance). For composite bolometric detectors, maximum pixel absorption efficiency requires that a reflecting back-short plate be positioned at $\lambda/4$ behind the array. The need to restrict the physical size of the array while maintaining a large pixel number limits the pixel size, which can be comparable to the wavelength. For an isolated detector this would result in a low absorption efficiency due to diffraction effects. However, capacitative coupling between the pixels results in a high overall efficiency for the array even with pixels smaller than the wavelength - the array appears to the incident beam as a continuous resistive sheet. Thus, the
radiation from the telescope arriving at the focal plane can be absorbed with very high efficiency, and this means that there is a potential increase in sensitivity over the feedhorn antenna coupled detector.

The main advantages of filled arrays (relative to $2F\lambda$ feedhorn arrays) are:

(i) they provide higher efficiency for mapping observations (as quantified in Section 5 below);

(ii) instantaneous full sampling of the image can be achieved by using pixels of $0.5F\lambda$ or smaller, obviating the need for jiggling or scanning;

(iii) for a $0.5F\lambda$ array, the beam profile on the sky can be slightly narrower for a given telescope size due to the stronger illumination of the outer parts of the telescope.

Disadvantages are:

(i) the background power per pixel is lower than for the larger feedhorn-coupled detectors, typically by a factor of $\sim 4$, giving a photon noise $NEP$ which is lower by a factor of 2, and thus more difficult to achieve;

(ii) the detectors are much more vulnerable to stray light due to the very wide pixel field of view - by a factor of $\pi F^2/4$, assuming a pixel field of view of $\pi$ sr;

(iii) the vulnerability to electromagnetic interference is also greater due to the “naked” array architecture;

(iv) more detectors are needed to fill a given field size: in the large-field limit, an array of $0.5F\lambda$ square pixels has 14.6 times more detectors than an array of close-packed $2F\lambda$ circular feedhorns, and 3.64 times more detectors than a $1F\lambda$ feedhorn array.
To date, the only operating instrument which has adopted this approach is SHARC\(^8\), in use on the Caltech Submillimeter Observatory (CSO). Filled bolometer arrays will be implemented in SHARC-2\(^9\), Sofia-HAWC\(^{10}\), Herschel-PACS\(^{11}\), and SCUBA-2\(^{12}\).

### 2.3 Assumptions

Filled array pixels larger than 0.5\(F\lambda\), or feedhorns smaller than 2\(F\lambda\), may also be used as a compromise between the extreme cases discussed above. In this work we consider the following four configurations: filled array with 0.5\(F\lambda\) pixels; filled array with 1\(F\lambda\) pixels; feedhorn array with 1\(F\lambda\) pixels; feedhorn array with 2\(F\lambda\) pixels. For ease of comparison, the performance characteristics of the other three options are normalized with respect to the 2\(F\lambda\) feedhorn case. In estimating the theoretical relative performance of the different array architectures, we make the following assumptions:

1. The point spread function (PSF) is purely diffraction limited. This will not be so in a real instrument but can be closely approximated in practice at FIR-submillimeter wavelengths [e.g., Ref. 13]. The assumption is effectively that the influence of imperfect PSF on sensitivity will be the same for both feedhorn and filled array options.

2. Beam profiles on the sky can be approximated by Gaussians in each case.

3. Thermal emission from three sources can contribute to the background power on the detectors: the telescope, the Earth’s atmosphere (if appropriate), and the instrument cold box.

4. The photon noise level is closely approximated by the Poissonian contribution (photon shot noise) - i.e., the Bose-Einstein term in the photon noise limited NEP [e.g., Ref. 14] can be
neglected. This simplifies the calculations and is reasonably well approximated in real
submillimeter instruments.

Detector center-center spacings are $0.5F\lambda$ or $1F\lambda$ for the filled array case and either $1F\lambda$ or
$2F\lambda$ for the feedhorn case. To account for a finite inter-pixel gap or horn wall thickness, the
active pixel sizes are assumed to be 5% less than the center-center distance: $0.475F\lambda$, $0.950F\lambda$, and $1.90F\lambda$.

Filled array pixels are square and have a broad field of view which we take to be
characterized by a solid angle of $\pi$ sr. A small portion of this field, determined by the focal
ratio of the final optics, $F$, views the telescope through an aperture in the cold box.

Feedhorns are single-moded (throughput $A\Omega = \lambda^2$).

The spectral passband is determined by a top-hat filter centered on wavelength $\lambda$ with a
bandwidth $\Delta\lambda$.

The optical efficiency of the instrument and the absorption efficiency of the detectors are the
same for all options.

There is no stray light or out-of-band radiation.

Observing overheads are negligible or equivalent for the different options.

Throughout, subscript 0 is used to refer to the case of $2F\lambda$ feedhorns, against which the other
array options are compared.
3. **Point source coupling efficiency, throughput, and beam profiles**

3.1 **Point source coupling efficiency for filled array pixels**

For an individual square pixel in a filled array, $\eta_{\text{pix}}$ is determined by the fraction of the power in the PSF that is contained within the pixel area, which may be calculated by integrating under the intercepted part of the PSF. This is plotted in Figure 2 for a diffraction limited system (the PSF is the Airy diffraction pattern). For 5% inter-pixel gap, $\eta_{\text{pix}}$ is 0.162 for the $0.5F\lambda$ case, and 0.495 for the $1F\lambda$ case.

3.2 **Throughput and background power per pixel for filled array pixels**

For square pixels with a field of view of total solid angle $\pi\text{sr}$, the throughput is:

for $0.5F\lambda$ pixels with 5% gap \[ A\Omega = [(0.5)(0.95)F\lambda]^2 \pi = 0.226 F^2 \lambda^2 \pi ; \quad (1) \]

for $1F\lambda$ pixels with 5% gap \[ A\Omega = [(1.0)(0.95)F\lambda]^2 \pi = 0.903 F^2 \lambda^2 \pi . \quad (2) \]

Most of this throughput views the cold box; the pixels view the telescope and sky with a top-hat beam of solid angle $\pi/(4F^2)$, corresponding to a fraction of the total throughput of $\alpha = 1/(4F^2)$. The throughput for the external background radiation is thus $0.177\lambda^2$ for $0.5F\lambda$ pixels and $0.709\lambda^2$ for $1F\lambda$ pixels.

The power per pixel scales with $A\Omega$, so the $1F\lambda$ pixel receives four times more background power than the $0.5F\lambda$ pixel. The photon noise limited $\text{NEP}$ is proportional to the square root of the background power and is consequently higher for the $1F\lambda$ pixel by a factor of 2.
3.3 Point source coupling efficiency for feedhorns

Figure 3 shows $\eta_{\text{pix}}$, the point source coupling efficiency, vs. horn aperture (in units of $\lambda/D$) for a smooth-walled conical horns.\(^{15}\) (This depends to some extent on the horn length - this curve is for an “aperture-limited” horn: i.e., the horn is sufficiently long that the beam profile is a good approximation to that of an infinitely long horn). The maximum efficiency is around 0.75 for horn aperture diameter close to $2\lambda/D$, corresponding to a physical diameter of $2F\lambda$. In practice, a peak value of $\eta_{\text{pix}} = 0.7$ is more realistic, taking into account finite horn length and wall thickness.\(^{16}\) For $1F\lambda$ horns, we adopt a value of $\eta_{\text{pix}} = 0.35$, also somewhat lower than the theoretical maximum. Although reducing the horn diameter lowers the efficiency of each horn, more horns can be accommodated in a given focal plane area. Smaller horns also have broader angular response, resulting in a larger fraction of the detector throughput being terminated on the cold box.

3.4 Throughput and background power per pixel for feedhorns

In the case of a feedhorn-coupled detector, the illumination of the telescope is approximately Gaussian, with an edge taper on the pupil that depends on the feedhorn antenna pattern and the details of the optical system. For single-moded feedhorns, the total horn throughput is $A\Omega = \lambda^2$. A fraction $\alpha$ views the telescope and sky and a fraction $(1 - \alpha)$ is terminated on the cold box. Figure 4 shows the telescope illumination fraction, $\alpha$, as a function of the edge taper for a Gaussian illumination of the pupil. Typical values for the edge taper would be in the range 7 - 10 dB for $2F\lambda$ horns and 1.5 - 3 dB for $1F\lambda$ horns. In this work we assume an edge taper for $2F\lambda$ of
8 dB, corresponding to $\alpha_0 = 0.83$. To first order, the main beam of a $1F\lambda$ feedhorn will be twice as wide as that of the $2F\lambda$, which corresponds to a 2-dB taper with $\alpha = 0.37$.

The background power received by the detector is proportional to the throughput. Compared to a $2F\lambda$ feedhorn-coupled detector, a $0.5F\lambda$ square pixel therefore receives less external power by a factor of $0.177/0.830 = 0.214$; and a $1F\lambda$ feedhorn-coupled detector receives less power by a factor of $0.370/0.830 = 0.446$. The contributions of the external background photon noise to the overall $NEPs$ are lower by the square roots of these numbers.

### 3.5 Beam profiles on the sky

For the feedhorn case, we take the beam pattern on the sky to be the Fourier transform of the amplitude illumination profile at the primary mirror. For the filled array, the beam profile is calculated as the convolution of the point spread function at the array focal plane with the pixel area. To compare the beam widths for the filled and feedhorn cases, we assume for simplicity that the point spread function is diffraction limited and that the effects of primary obscuration can be neglected (to first order, departures from these assumptions will have equivalent effects on the beam profiles for the two cases).

Figure 5 shows the FWHM beam-width (in units of $\lambda/D$) as a function of edge taper for the feedhorn case and pixel size for the filled absorber case. For the feedhorn, increasing the edge taper broadens the beam on the sky because the outer portion of the aperture is less efficiently illuminated. For the filled pixel, the beam gets broader as the pixel gets larger because the profile is determined by the convolution of the PSF with the pixel. A feedhorn edge taper of 8 dB ($2F\lambda$), results in a beam only about 5% wider than the $0.5F\lambda$ filled array beam-width, and for
the 2-dB edge taper \((1F\lambda)\), the beam is slightly narrower. In comparing the \(2F\lambda\) or \(1F\lambda\) feedhorns with \(0.5F\lambda\) filled pixel case, we therefore assume that the differences in beam-width are negligible. The choice of \(1F\lambda\) filled array pixels does, however, result in a more significant broadening of the beam.

4. Signal-to-noise ratios and relative observing speed

4.1 Power levels on the detectors and overall \(NEP\)

The total radiant power absorbed by each pixel has four contributions as follows.

- **the telescope:**
  \[ P_T = \alpha A \Omega B_v \left( T_T \right) \Delta \nu \epsilon_T \eta_o \eta_d \]  
  \((3a)\)

- **the atmosphere:**
  \[ P_A = \alpha A \Omega B_v \left( T_A \right) \Delta \nu \epsilon_A \left(1 - \epsilon_T \right) \eta_o \eta_d \]  
  \((3b)\)

- **the astronomical sky:**
  \[ P_S = \alpha A \Omega B_v \left( T_S \right) \Delta \nu \left(1 - \epsilon_A \right) \left(1 - \epsilon_T \right) \eta_o \eta_d \]  
  \((3c)\)

- **the instrument cold box:**
  \[ P_C = \left(1 - \alpha \right) A \Omega B_v \left( T_C \right) \Delta \nu \eta_o \eta_d \]  
  \((3d)\)

We can write the total power as

\[
P_{\text{tot}} = \alpha A \Omega \Delta \nu \eta_o \eta_d \left[ B_{\text{ext}} + \frac{1 - \alpha}{\alpha} B_{\text{int}} \right],
\]  
\((4)\)

where

\[
B_{\text{ext}} = \epsilon_T B_v \left( T_T \right) + \epsilon_A \left(1 - \epsilon_T \right) B_v \left( T_A \right) + \left(1 - \epsilon_A \right) \left(1 - \epsilon_T \right) B_v \left( T_S \right)
\]  
\((5)\)

is the external surface brightness (the sum of the telescope, atmosphere and sky contributions), and

\[
B_{\text{int}} = B_v \left( T_C \right)
\]  
\((6)\)

is the internal surface brightness of the instrument cold box.

The photon noise limited \(NEP\), referred to the power absorbed by the detector, is given by
\[ \text{NEP}_{\text{ph}} = \left[ 2P_{\text{tot}}h\nu \right]^{1/2}. \]  

(7)

The overall NEP, referred to the power absorbed by the detector, is

\[ \text{NEP}_{\text{tot}} = \left[ \text{NEP}_{\text{ph}}^2 + \text{NEP}_{\text{det}}^2 \right]^{1/2}. \]  

(8)

Letting \( \text{NEP}_{\text{det}} = \gamma \text{NEP}_{\text{ph}} \), we have

\[ \text{NEP}_{\text{tot}} = \text{NEP}_{\text{ph}} \left[ 1 + \gamma^2 \right]^{1/2}. \]  

(9)

### 4.2 Measurement of sky intensity distribution (extended source)

For observation of a source extended with respect to the beam, the signal power, \( P_S \), absorbed by a detector is that due to the astronomical sky brightness, as given by equation (3c). After an integration time, \( \tau \), the signal-to-noise ratio, \( \sigma \), is

\[ \sigma = \frac{P_S (2\tau)^{1/2}}{\text{NEP}_{\text{tot}}}. \]  

(10)

We then have, from (4), (7) and (9),

\[ \sigma = \frac{B_V T_S (1 - \varepsilon_A) (1 - \varepsilon_T) (\alpha \lambda \Omega \Delta \nu \eta_o \eta_d \tau)^{1/2}}{\left[ h\nu (1 + \gamma^2) \left( B_{\text{ext}} + \frac{1 - \alpha}{\alpha} B_{\text{int}} \right) \right]^{1/2}}. \]  

(11)

For simplicity in comparing the different arrays, we can lump together into a constant, \( K \), all of the quantities that are assumed to be independent of the detector type:

\[ \sigma = K \left[ \frac{\alpha \lambda \Omega \tau}{(1 + \gamma^2) B_{\text{ext}} + \frac{1 - \alpha}{\alpha} B_{\text{int}}} \right]^{1/2}. \]  

(12)
The S/N achieved, relative to the $2F\lambda$ feedhorn array, with one of the other options in a given integration time for one detector is

$$\frac{\sigma}{\sigma_0} = \left[ \frac{\alpha \lambda \Omega}{\alpha_0 \lambda \Omega_0} \right]^{1+\gamma_0^2} \left[ B_{\text{ext}} + \frac{1-\alpha_0}{\alpha_0} B_{\text{int}} \right]^{1/2} \left[ B_{\text{ext}} + \frac{1-\alpha}{\alpha} B_{\text{int}} \right].$$

(13)

The relative observing speed for one detector is proportional to $(\sigma/\sigma_0)^2$. If we consider maps of a given area made with multi-detector arrays, then for an array with $\beta$ times more detectors than the $2F\lambda$ array, the mapping speed will also be enhanced by a factor of $\beta$.

It is convenient to characterize the influence of the instrument internal background in terms of the ratio of the internal to external brightness: $R = B_{\text{int}}/B_{\text{ext}}$. From equation (13), the relative speed for the complete map may then be written as

$$\frac{\text{Speed}}{\text{Speed}_0} = \beta \left[ \frac{\sigma}{\sigma_0} \right]^2 = \beta \left[ \frac{\alpha}{\alpha_0} \right]^2 \left[ \frac{\lambda \Omega}{\lambda \Omega_0} \right]^{1+\gamma_0^2} \left[ \frac{\alpha_0 + (1-\alpha_0)R}{\alpha + (1-\alpha)R} \right].$$

(14)

In the completely external background limited case ($\gamma = \gamma_0 = 0; R = 0$), the mapping speed ratio is just the ratio of the detector numbers multiplied by the ratio of the external throughput per detector for the two cases.
4.3 Observation of a point source on-axis

In this case the requirement is to measure the flux density of the point source, and the coupling efficiency of the individual detectors to the point spread function is important. The background power and photon noise limited NEP are as given above in equations (4) and (7). The signal power absorbed by the on-axis detector is.

\[ P_S = S_v A_T \Delta \nu (1 - \epsilon_A)(1 - \epsilon_T) \eta_0 \eta_d \eta_{\text{pix}}. \]  

Equation (10) then gives

\[ \sigma = \frac{S_v A_T (1 - \epsilon_A)(1 - \epsilon_T) (\Delta \nu \eta_0 \eta_d \tau)^{1/2}}{\sqrt{A_\Omega h \nu (1 + \gamma^2) [\alpha B_{\text{ext}} + (1 - \alpha) B_{\text{int}}]^{1/2}}} \]  

We can again combine together all of the quantities that are assumed to be independent of the array architecture:

\[ \sigma = K_2 \eta_{\text{pix}}^{1/2} \frac{\tau^{1/2}}{\sqrt{A_\Omega (1 + \gamma^2) [\alpha B_{\text{ext}} + (1 - \alpha) B_{\text{int}}]^{1/2}}} \]  

where \( K_2 \) is another constant.

For the feedhorn arrays and the \( 1F\lambda \) filled array, the main beams of the nearest neighbor detectors are too far away to collect any appreciable power from a point source, so the measurement is by the on-axis detector only. No jiggle pattern is needed, and the total available integration time is used on-source. In the case of the \( 0.5F\lambda \) filled array, the signals from the eight neighboring pixels can be co-added to improve the S/N, with the signals weighted in accordance with the beam pattern. By convolution of the diffraction limited PSF with the square
pixel area, it can be shown that this co-addition provides an enhancement in S/N by a factor of 1.58 compared to value given by equation (17) for the on-axis detector alone.

The relative observing speed ratio is given by the squares of the S/N ratio. Comparing the observing speed achieved for a given integration time (for the on-axis detector alone) with that for the $2F\lambda$ case, we therefore have

$$\frac{Speed}{Speed_0} = f \left[ \frac{\sigma}{\sigma_0} \right]^2 = f \left[ \frac{\eta_{\text{pix}}}{\eta_{\text{pix}0}} \right]^2 \left[ \frac{A\Omega_0}{A\Omega} \right] \left[ \frac{1 + \gamma_0^2}{1 + \gamma^2} \right] \left[ \frac{\alpha_0 + (1 - \alpha_0)R}{\alpha + (1 - \alpha)R} \right].$$

(18)

where the factor $f = 1.58^2 = 2.5$ for the $0.5F\lambda$ case, and $f = 1$ for the other cases.

4.4 Seven-point observation of a point source with the feedhorn option

Should the pointing accuracy or knowledge of the source position be such that one cannot rely on blind pointing to make an accurate measurement of a point source, then, for the feedhorn option, it is necessary to carry out a small map around the source. This reduces the S/N for a given integration time because the time must be shared between several positions. The most efficient approach is to perform a five, seven, or nine-point map in which the nominal and adjacent positions around it are visited in turn by a detector. The spacing, $\Delta \theta$, should be larger than the maximum expected pointing error or the uncertainty in the source position. Here we assume that a 7-point observation is carried out, with the signals from the seven map points co-added to derive the total flux density, and compare the final S/N with the S/N that would be obtained if the pointing were good enough to devote all of the integration time to one position.
Compared to the value for the central position alone, the total signal is increased by a factor of

\[ 1 + 6 \exp\left[ -\frac{2\ln(2)^{1/2} \Delta \theta}{\theta_{\text{FWHM}}} \right]^2 \].

The noise per position is increased by a factor of \( 7^{1/2} \) compared to that for a single long integration because the integration time is shared between the seven positions; and the final noise level is increased by a further \( 7^{1/2} \) through the co-addition of the seven signals. The final S/N is therefore reduced by a factor of

\[ 7 \left[ 1 + 6 \exp\left[ -\frac{2\ln(2)^{1/2} \Delta \theta}{\theta_{\text{FWHM}}} \right]^2 \right]. \]

This square of this factor, representing the loss in observing speed, is plotted against the step size (normalized to the beam FWHM) in Figure 6. For a typical value of \( \Delta \theta = 0.3 \), performing the 7-point results in an observing speed reduction by a factor of 0.66.

### 4.5 Extraction of point sources from maps

An important scientific goal for imaging submillimeter instruments is to carry out surveys of unexplored areas of sky and to detect faint point sources in the maps. Such observations can be made either by taking data on-the-fly while scanning the telescope continuously, or by raster scanning. In the former case, spatial modulation of the signal can be implemented either by chopping the field of view or by choosing a scan rate such that the signal frequencies are above the 1/f knee of the system. In order to extract optimally all the necessary information on the sky and on the characteristics of the detector system, a "dithering" scheme involving more complex modulation of the beam may be implemented.
If modulation is implemented by scanning alone (without chopping or dithering), then the scan rate must also be such that the beam crossing time is long compared to the detector time constant to avoid loss of angular resolution in the scan direction. Chopping and/or dithering can also be carried out in making maps. In these modes, the individual detector signals must be explicitly recorded: differencing prior to recording will add significantly to the confusion noise due to the larger effective beam area, increasing the confusion limit by a factor of ~1.6.

Scanning observations with feedhorn arrays produce a fully sampled image of the sky covered by each individual scan provided the scan direction is chosen to give the necessary overlap between the beams. For chopped observations with feedhorn arrays, a “jiggle-pattern” must be performed to get a fully sampled map.

Notwithstanding any differences in the observing modes, it is possible to determine generically the relative mapping speeds of the feedhorn and filled array architectures. Consider a fully-sampled map of a given area with a certain total integration time and a fixed spacing between the samples. In practice the sampling grid may be more complicated, but that will have little or no effect on the result of this comparison. Regardless of the exact details of the observing modes, in the filled array case we have $\beta$ times more integration time per sample than for the feedhorn case. If the map is critically sampled ($0.5\lambda/D$ spacing) then the filled array generates it purely by spatial multiplexing while the feedhorn array does it by a combination of spatial and temporal multiplexing. If it is over-sampled (say, $0.25\lambda/D$) then both arrays use a combination of spatial and temporal multiplexing. In any case, what determines the mapping speed is the final S/N per map point, which is considered below. For simplicity, we assume that the map contains a point source that happens to be centered on one of the map points, and that the small
difference in the beam widths between the filled array and feedhorn-coupled systems can be neglected.

Consider a map with integration time $\tau$ per map position. Let the map contain an isolated point source coincident with one of the map points, with signal $S_a$ at that position. Let $\Delta S$ be the noise level in each map position. Let $\sigma_a = S_a/\Delta S$ be the S/N for the central position (given by equation 17), and let $n$ appropriate map points be co-added to enhance S/N on the point source.

The signal in pixel $i$ is

$$S_i = S_a \exp \left[ -\frac{\left( 2 \ln(2) \right)^{1/2} \Delta \theta_i }{\theta_{\text{FWHM}}} \right]^2, \quad (19)$$

where $\Delta \theta_i$ is the angular offset from the source. The final signal level is

$$S_{\text{tot}} = \sum S_i = K_3 S_a, \quad (20)$$

where $K_3$ is a constant that depends on the grid spacing and $\theta_{\text{FWHM}}$. The final noise level is

$$\Delta S_{\text{tot}} = n^{1/2} \Delta S. \quad (21)$$

and the final S/N is thus

$$\sigma = \frac{K_3}{n^{1/2}} \sigma_a = \frac{K_2 K_3 \eta_{\text{pix}} \tau^{1/2}}{n^2 \alpha \Omega \left( 1 + \gamma^2 \right) \left[ B_{\text{ext}} + \frac{1-\alpha}{\alpha} B_{\text{int}} \right]}^{1/2}. \quad (22)$$

For an array with $\beta$ times more detectors than the $2F\lambda$ case, the integration time per point is $\beta$ times longer. Taking the square of the ratio of the S/N values gives the relative mapping speed with respect to the $2F\lambda$ feedhorn case:
\[
\frac{\text{Speed}}{\text{Speed}_0} = \left[ \frac{\sigma}{\sigma_0} \right]^2 = \beta \left[ \frac{\eta_{\text{pix}}}{\eta_{\text{pix0}}} \right]^2 \left[ \frac{\Lambda \Omega}{\Lambda \Omega_0} \right] \left[ \frac{1 + \gamma_0^2}{1 + \gamma^2} \right] \left[ \frac{\alpha_0 + (1 - \alpha_0)R}{\alpha + (1 - \alpha)R} \right],
\]

which is the same as equation (18) for a point source on-axis except that the factor \( f \) is replaced by \( \beta \).

5. Observing speed comparison

5.1 Case of zero instrument background

In this section we consider the case in which the internal background due to the instrument cold box can be neglected (i.e., \( R \approx 0 \)). This is a reasonable assumption for all of the options at far infrared and submillimeter wavelengths but is not necessarily valid for filled array detectors at millimeter wavelengths. The case of non-negligible instrument background is considered below in Section 5.2. The array parameters derived in Section 3 for the four cases are listed in Table 1. These have been used to calculate the relative observing speed using the equations derived in Section 4. The values of \( \gamma \) assume that the inherent detector \( \text{NEP} \) is the same for all options.

(a) Purely background-limited case

For completely background limited detectors, the parameter \( \gamma \) is zero (i.e., \( \text{NEP}_{\text{det}} << \text{NEP}_{\text{ph}} \)) in all cases. The observing speed ratios, as defined in Section 4, are then as given in Table 2. For extended source observation, the filled arrays are the fastest options, with no difference in principle (barring the small difference in angular resolution) between the 0.5\( F\lambda \) and 1\( F\lambda \) cases. The potential enhancement in observing speed over the 2\( F\lambda \) feedhorn case is about a factor of 3.
For point source extraction from a map, the $0.5F\lambda$ filled array is faster than any of the other options, with a speed advantage of 3.6 compared to the $2F\lambda$ feedhorn case. The two $1F\lambda$ options have comparable speed at around a factor of 2 faster than the $2F\lambda$ case. For observation of a known point source with good pointing accuracy, the $2F\lambda$ feedhorn option is significantly better than any of the others. If a seven point needs to be implemented, then the sensitivity is still comparable to that of the $0.5F\lambda$ filled array case. The $1F\lambda$ feedhorn case is poorly optimized for this kind of observation.

(b) Partly detector noise limited case

A more realistic assumption is that the detector NEP is finite, so that $\gamma$ is non-zero. The observing speed ratios are plotted vs. $\gamma$ in Figures 7, 8 and 9, covering the range $\gamma = 0 - 1$, where 0 corresponds to the purely background-limited case and 1 corresponds to $NEP_{det} = NEP_{ph}$.

For an extended source (Figure 7) the filled array speed advantage holds up best for the $1F\lambda$ case because the background level is similar to that for the $2F\lambda$ feedhorns. The speed advantage for the $0.5F\lambda$ array declines to around a factor of 2 for $\gamma = 1$. This is because the lower background on the filled array detectors means that, as $NEP_{det}$ increases, the departure from background limited operation is greater than for the feedhorn-coupled detectors: to take advantage of the potential observing speed advantage, more sensitive detectors are needed. For point source extraction from a map (Figure 8), the advantage of the $0.5F\lambda$ option again decreases to around a factor of 2 for $\gamma = 1$. The $1F\lambda$ options have comparable sensitivity over the range of backgrounds. For observation of a point source on-axis (Figure 9), the $2F\lambda$ option is the fastest, even if a 7-point has to be executed, and the relative advantage becomes slightly greater as $NEP_{det}$
increases. As for the other observations, the relative performance of the $1F\lambda$ filled array remains fairly uniform over the range of backgrounds.

### 5.2 Non-zero instrument background

Because filled array pixels have a much larger throughput than feedhorn coupled detectors, they are prone to collect much more background power from the instrument itself. At millimeter wavelengths, this can become a significant or even dominant contribution to the photon noise unless the cold box surrounding the detectors is maintained at a very low temperature. Important potential applications are cosmic background radiation observations and deep extragalactic surveys in the 2 - 3 mm region. To examine the impact of the instrument background, we consider the dependence of the observing speed on $R$, the ratio of the instrument cold box brightness to the external brightness. Figure 10 shows the extended source observing speed vs. $R$ for the purely background-limited case ($\gamma = 0$). All curves are normalized to the case of the $2F\lambda$ array with $R = 0$. The $2F\lambda$ case is very insensitive to the instrument cold box emission because the highly directional angular response of the feedhorn illuminates the pupil preferentially. Even the broader $1F\lambda$ feedhorn beam results in only a small degradation in speed provided $R < 10\%$. However, for the filled arrays, the speed advantage is rapidly eroded by instrument background photon noise for $R > 0.1\%$, and has vanished entirely for $R > 2\%$. The mapping speed advantage for the other kinds of observation is similarly sensitive to the background instrument background (but the curves for the two filled array options are identical only for the particular case shown here of an extended source with zero detector NEP).
Figure 11 shows the brightness ratio as a function of cold box temperature for two typical examples:

(i) a ground-based experiment at $\lambda = 3 \text{ mm}$ with $T_T = 280 \text{ K}$, $\epsilon_T = 0.05$, $T_A = 250 \text{ K}$, $\epsilon_A = 0.05$, $T_s = 2.73 \text{ K}$;

(ii) a space-borne experiment at $\lambda = 2 \text{ mm}$ with $T_T = 60 \text{ K}$, $\epsilon_T = 0.01$, $T_A = 0$, $T_s = 2.73 \text{ K}$.

Retaining a factor of 2 advantage in speed for the filled array options requires $R < 0.006$, so the temperature of the detector enclosure must be maintained at less than $\sim 1.5 \text{ K}$ (ground-based) or $\sim 1 \text{ K}$ (space experiment). We note that these results are optimistic for the filled arrays in that they assume that the detector NEP is zero and that stray light is negligible. In addition, the strong temperature dependence of the cold-box background in the Wien region of the black-body spectrum would dictate either lowering the temperature further or implementing very precise temperature control.

6. Conclusions

In addition to operational advantages, filled bolometer arrays offer, for a given field area, improved sensitivity for mapping observations at the expense of larger detector numbers. In order to take full advantage of the fully-sampled filled array architecture, the detectors must be operated close to the background limit. In that limiting case, the fully-sampled filled array is 3.6 times faster than the traditional $2F\lambda$ feedhorn array for the extraction of point sources from mapping observations. For a given number of detectors, feedhorn-coupled architectures provide better mapping speed than filled arrays, at the expense of a larger field of view. The $2F\lambda$ feedhorn provides the best possible sensitivity for observations of a known point source.
the complexity of bolometer instruments, practical considerations such as stray light and RF suppression, multiplexing capabilities, power dissipation, available data rate, instrument cryogenic design and temperature stability, etc., may be important in deciding between the various options.
