The main thrust of this paper is to provide a novel method for determining the character of the quantum system. The novel method is based on the direct observation of the quantum state, which is achieved by applying a suitable operator to the system. The operator is chosen such that it is a Hermitian operator, which ensures that the eigenvalues of the operator are real. The method is demonstrated on a simple quantum system, the hydrogen atom, and it is shown that the method is able to determine the character of the quantum state with high accuracy.

\begin{equation}
H |\psi\rangle = E |\psi\rangle
\end{equation}

The Hamiltonian of the quantum system is given by $H$, the state of the system is represented by $|\psi\rangle$, and the eigenvalue is $E$. The operator $H$ is chosen such that it is a Hermitian operator, which ensures that the eigenvalues of the operator are real. The method is demonstrated on a simple quantum system, the hydrogen atom, and it is shown that the method is able to determine the character of the quantum state with high accuracy.

Over the last two decades, a great deal of insight has been gained into the nature of quantum systems. However, there are still many questions that remain unanswered. One of the most important questions is the nature of the quantum state. The quantum state is a fundamental concept in quantum mechanics, and it is the basis for all quantum phenomena. The quantum state is a mathematical object that describes the state of a quantum system. The quantum state is a complex vector in a Hilbert space, and it is characterized by a set of eigenvalues.

The quantum state is a complex vector in a Hilbert space, and it is characterized by a set of eigenvalues. The eigenvalues are the squares of the absolute values of the components of the quantum state, and they are the fundamental quantities that describe the state of a quantum system. The eigenvalues are used to determine the character of the quantum state, and they are the basis for all quantum phenomena. The quantum state is a complex vector in a Hilbert space, and it is characterized by a set of eigenvalues. The eigenvalues are the squares of the absolute values of the components of the quantum state, and they are the fundamental quantities that describe the state of a quantum system. The eigenvalues are used to determine the character of the quantum state, and they are the basis for all quantum phenomena.
to arbitrary accuracy $\mathbb{1} \geq \mathbb{2} \geq \mathbb{3} \geq \mathbb{4}$. Here we observe that $\langle \psi_p(n) | \psi_q(n) \rangle = \langle \psi(n) | \psi(0) \rangle = \langle \psi_f | 0 \rangle$, where the state $\psi_f$ is obtained by time-reversing the initial state preparation $\psi_f = U^\dagger |\psi(0)\rangle$. The magnitude of $O(n)$ is then determined from sampling the population of the state $|0\rangle$. The entire algorithm therefore scales as $\text{Poly}(n)$. 

Recently, Jacquod and coworkers \cite{Jacquod2009} observed that for $|\psi(0)\rangle = |v_o\rangle$, an initial eigenstate of $U$ with eigenphase $\phi_o$, the fidelity relates to the local density of states (LDOS), $\eta(\phi_o - \phi_m') = | \langle v_o | v_m' \rangle |^2$, via Fourier transform, 

$$O(n) = \frac{1}{n} \sum_{m} \eta(\phi_o - \phi_m') \exp(-i(\phi_o - \phi_m') n).$$

(2)

In the above $|v_m'\rangle$ are eigenstates of the perturbed map $U_p U |v_m'\rangle = \exp(-i\phi_m') |v_m'\rangle$. These observations locate the decay of $O(n)$ in an existing theoretical regime. In the non-perturbative regime $\sigma/\Delta \gg 1$, where $\sigma = \delta^2 V_{nm'}$ denotes a typical off-diagonal matrix element and $\Delta$ is the average level spacing, previous work suggests that when the perturbed system is complex the LDOS is typically Lorentzian \cite{Izrailev1989,Hamma2013},

$$\eta(\phi_o - \phi_m') \propto \frac{\Gamma}{(\phi_o - \phi_m')^2 + (\Gamma/2)^2}$$

(3)

with width $\Gamma = 2\pi\sigma^2/\Delta$ determined by the Fermi golden rule (FGR). From \cite{Izrailev1989} and \cite{Hamma2013} one expects the exponential decay,

$$O(n) \simeq \exp(-\Gamma n).$$

(4)

The onset of the exponential decay \cite{Izrailev1989} has been confirmed recently in a few classically chaotic models \cite{Hamma2013,Hamma2014}. However, this case of integrable $U$ the situation is less clear since under some perturbations the LDOS is known to take on a Lorentzian shape \cite{Izrailev1989,Hamma2013}. Below, we examine which statistical properties of the unperturbed system lead to the FGR decay, and how this characteristic decay depends on the properties of the perturbation operator. This approach is motivated by the context of QIP simulation, in which the eigenbasis of this perturbation may be mapped onto an arbitrary basis of the simulated system $U$. \cite{Izrailev1989}. Our choice of perturbation eigenvalue structure is motivated from the perspective of quantum control studies. Specifically, we consider

$$U_p = \Pi_{j=1}^{n_q} \exp(-i\delta \sigma_z^2/2),$$

(5)

where $\sigma_z$ is the usual Pauli matrix and \cite{Izrailev1989} therefore corresponds to a collective rotation of all the qubits by an angle $\delta$. Eq. \cite{Izrailev1989} is a model of coherent far-field errors \cite{Izrailev1989}, and for this type of error model a better understanding of the fidelity decay is a subject of intrinsic interest.

As a first test of the LDOS/FGR framework in the case of the qubit perturbation \cite{Izrailev1989} we evaluate the fidelity decay for a map $U = U_{\text{CUE}}$ drawn from the circular unitary ensemble (CUE). These matrices form an established model for classically fully chaotic time-periodic systems (without additional symmetries) since these systems (almost always) exhibit the same characteristic (Wigner-Dyson) spectral fluctuations and eigenvector statistics as the CUE \cite{Mehta2004}. The randomness of the system eigenvectors enables a system-independent estimate of the rate $\Gamma$ of the FGR decay. Since the components of random eigenstates are distributed uniformly over the basis states and uncorrelated with the distribution of eigenvalues, the second moment of the matrix elements $V_{mn}$ may be directly evaluated,

$$\langle V_{mn}^2 \rangle = \frac{\lambda^2}{N}$$

(6)

assuming $\lambda = 0$ and where $\lambda^2 = N^{-1} \sum_{k=1}^{N} \lambda_k^2$ denotes the variance of the eigenvalues of $V$. As a result, the rate of the FGR decay is determined by the eigenvalues of the perturbation,

$$\Gamma = \delta^2 \lambda^2,$$

(7)

where we have used $\Delta = 2\pi/\gamma$. For the qubit perturbation \cite{Izrailev1989} the variance of the eigenvalues has a simple form,

$$\lambda^2 = \frac{1}{N} \sum_{k=0}^{n_q} \left( \frac{2k-n_q}{2} \right)^2 C_k^{n_q},$$

(8)

where the $C_k^{n_q}$ are binomial coefficients. Using our RMT estimate \cite{Izrailev1989}, for $n_q = 10$, the rate is,

$$\Gamma = 2.59 \delta^2.$$

(9)

While a CUE map may be generated on a QIP using the gate decomposition devised in Ref. \cite{Izrailev1989}, for our numerical study we construct $U = U_{\text{CUE}}$ directly from the eigenvectors of a random Hermitian matrix. Since computational basis states are easiest to prepare in the QIP setting, we consider the fidelity decay for both single-computational basis states and averages over 50 such states. The behaviour of the fidelity decay for a matrix typical of CUE is displayed in Fig. \cite{Izrailev1989}. The three perturbation values displayed in the figure are chosen near the onset of the non-perturbative regime ($\delta > 0.1$) and it is evident that the fidelity decay even for individual computational basis states exhibits FGR decay \cite{Izrailev1989} at the expected rate. The FGR decay persists for a time-scale $\Gamma^{-1} \log(N)$ until saturation at a time-average that decreases as $1/N$.

We next consider $O(n)$ for the Gaussian unitary ensemble (GUE) in order to clarify the relationship between the FGR decay and the distinct statistical features of RMT that represent signatures of quantum chaos. The GUE consists of Hermitian matrices with independent
elements drawn randomly with respect to the unique unitarily-invariant measure. GUE forms the relevant RMT model for the important class of chaotic or complex autonomous Hamiltonian systems that are unrestricted by any additional symmetries. We may examine the sensitivity to perturbations for the GUE by constructing the unitary operator $U_{\text{GUE}} = \exp(-iH_{\text{GUE}}\tau)$, where $\tau$ is a time-delay between perturbations. We consider the same perturbation as for the CUE case. For sufficiently small $\tau$ the propagator approaches identity and the overlap decay is dominated by the perturbation operator, $O(n) = \langle (\exp(-i\delta V))^2 \rangle + O(\delta^2 \tau^2 n^2)$. This behaviour is demonstrated in Fig. 4 for $\tau = 0.001$ and $\tau = 0.01$ and with $\delta = 0.3$. For larger values of $\tau$ the fidelity decay under $U_{\text{GUE}}$ obeys the FGR with the RMT rate $\mathcal{A}$.

The important point is that for sufficiently large $\tau$ the eigenphases of $U_{\text{GUE}}$ become spread pseudo-randomly in the interval $[0, 2\pi]$. Under these conditions the eigenphases of the map $U_{\text{GUE}}$ exhibit the Poissonian spectral fluctuations that are characteristic of classically integrable (time-periodic) systems. We checked the nearest-neighbor spacing distribution of $U_{\text{GUE}}$ and found that for $\tau = 100$ the statistics are in excellent agreement with the Poissonian distribution $P(s) \propto \exp(-s)$ (see inset to Fig. 4). However, the eigenvectors of $U_{\text{GUE}}$ are random (by construction) and independent of $\tau$ (for finite $\tau$). From these observations it is clear that the presence of Wigner-Dyson spectral fluctuations in the implemented $U$, which comprises the only basis-independent criterion of quantum chaos, is not actually necessary for the onset of exponential (FGR) decay at the rate $\mathcal{A}$. This suggests that it is the RMT statistics of the eigenvectors of $U$ that lead to the FGR decay with the RMT rate.

We next consider the fidelity decay for the quantum kicked top, which is an exemplary dynamical model of quantum chaos. The kicked top is a unitary map $U_{\text{QKT}} = \exp(-i\pi J_y/2)\exp(-i\pi J_z^2/\hbar)$ acting on the Hilbert space of dimension $N = 2^j + 1$ associated with an irreducible representation of the angular momentum operator $J$. In previous fidelity decay and LDOS studies the choice of perturbation has usually been tied to a physical coordinate of the system $U$. We first follow this convention and identify the eigenbasis of the perturbation with the eigenbasis $|m_j\rangle$ of the system coordinate $J_z$ (where $m_j = \{j, \ldots, -j\}$). In Fig. 8 we compare the fidelity decay for the chaotic and regular regimes of the kicked top for averages over 50 initial computational basis states. The fidelity decay for the chaotic top ($k = 12$) is well described by the FGR prediction $\mathcal{A}$ and the RMT rate $\mathcal{B}$ whereas the regular top ($k = 1$) shows a slower non-exponential decay rate. Similarly, if we associate the perturbation eigenbasis with the basis of the $J_y$ coordinate, the fidelity decay for the chaotic top remains in agreement with the RMT rate and the regular top again exhibits non-exponential decay, though in this case with a faster decay than the RMT rate $\mathcal{B}$. However, we now demonstrate that an exponential decay at the RMT rate arises even for the regular kicked top when the qubit perturbation $\mathcal{B}$ is diagonal in a generic basis relative to the eigenbasis of $U_{\text{QKT}}$. Specifically, we leave the perturbation eigenvalue spectrum unchanged but set

$$U_p = T \left[ \Pi_j \exp(-i\delta_j^2/2) \right] T^{-1},$$

where $T$ is drawn from CUE. As demonstrated in the inset to Fig. 8 under this type of perturbation the fidelity decay for the regular top is indistinguishable from that of the chaotic top and is very accurately described by the FGR at the RMT rate $\mathcal{A}$.
FIG. 3: Decay of $O(n)$ for the kicked top in chaotic regime ($k = 12$) averaged over 50 computational basis states, with the perturbation eigenbasis mapped to the eigenbases of $J_z$ (dash lines) and $J_y$ (chain lines) compared to the FGR decay (solid lines) at the RMT rate $\Omega$ for $\delta = (0,1,0.3)$ (top to bottom). Lines with circles and squares are for the regular kicked top ($k = 1$) with the perturbation eigenbasis tied to the $J_z$ and $J_y$ coordinate bases respectively (for $\delta = 0.1$). Inset: Average fidelity decay for regular kicked top ($k = 1$), when the qubit perturbation is in a random eigenbasis and with $\delta = (0,1,0.3)$ (dashed lines), compared to the FGR/RMT rate (solid lines).

The sensitive dependence of the type of fidelity decay on the eigenbasis of the applied perturbation suggests a close connection with the basis-dependence of the eigenvector statistics of classically regular quantum models. Expressed in a generic quantum basis, the eigenvectors of any quantized classical system $U$ will have randomly (Gaussian) distributed components. In contrast, in the eigenbases of the system coordinates the components of classically chaotic and integrable systems are known to be different, with the former Gaussian distributed and the latter exhibiting substantial deviation from the canonical Gaussian distribution. In light of this connection, in the case of quantized classical models we infer that exponential (non-exponential) fidelity decay can be correlated with the presence (absence) of characteristic RMT spectral fluctuations in the unperturbed system provided that the applied perturbation commutes with a system coordinate.

In summary, we have shown that the fidelity decay may be measured efficiently on a QIP. We then examined which statistical properties of the unperturbed system determine the type and rate of the decay. In the case of random unitary and Hermitian matrices, as well as a classically chaotic dynamical model, we have shown that the fidelity decays exponentially with a characteristic rate given precisely by the variance of the perturbation’s eigenspectrum. The occurrence of the exponential decay is not directly dependent on the Wigner-Dyson fluctuations of the unperturbed spectrum, but does depend sensitively on the RMT statistics of the system eigenvectors in the eigenbasis of the applied perturbation. Hence, the fidelity decay for both classically regular and chaotic dynamical systems is given by the FGR under all but a small subset of unitary perturbation operators. In the case of classical models, we conclude that the fidelity decay provides a reliable indicator of RMT statistics (quantum chaos) in the unperturbed system only when the applied perturbation is restricted to the subset of perturbations that commute with a classical coordinate.

We are grateful to K. Zyczkowski for suggesting the relevance of the eigenvector statistics. Ph. Jacquod, E.M. Fortunato, C. Ramanathan, and T.F. Havel for helpful discussions, and DARPA and the NSF for financial support.
