THE VERTICAL STRUCTURE OF THE HALO ROTATION

T.D. Kinman\textsuperscript{1,2}, C. Cacciari\textsuperscript{3}, A. Bragaglia\textsuperscript{3}, A. Buzzoni\textsuperscript{4} and A. Spagna\textsuperscript{5}

Abstract. New GSC-II proper motions of RR Lyrae and Blue Horizontal Branch (BHB) stars near the North Galactic Pole are used to show that the Galactic Halo 5 kpc above the Plane has a significantly retrograde galactic rotation.

1 Introduction

Recent determinations of the mean rotation ($<V>$) of the field component of the Galactic halo are summarized in Table 1 for stars within 2 kpc of the Sun and in Table 2 for stars at distances ($Z$) more than 4 kpc above the Plane. Metal-poor subdwarfs are mostly discovered by their high proper motions and so a substantial correction for kinematic bias is required if they are to be used as tracers. No such kinematic bias correction is needed for RR Lyrae stars or halo K giants (discovered from objective prism surveys) but (as also for the subdwarfs) a correction is needed for a thick disk component. The first four estimates in Table 1 use somewhat different approaches to this disk correction and all give values of $<V>$ for the halo in the solar neighbourhood that are close to that of the local circular velocity of $-220$ km/s (Kerr & Lynden-Bell 1986); so there is some consensus that the local halo does not rotate.

The situation is different for estimates of $<V>$ for halo stars out of the Plane (Table 2). The only estimate for an in situ out-of-plane sample is that of Majewski (1992) and Majewski et al. (1996) who found $<V>$ to be 55 km/s retrograde. The estimates of Carney (1999) and Chiba & Beers (2000) come from stars whose calculated orbits take them more than 4 kpc from the plane; they find no rotation.

or a slightly prograde rotation for these stars. The present work attempts to resolve this discrepancy; it grew from earlier studies of halo stars in the North Galactic Cap (Kinman et al. 1996) which confirmed the streaming motion (in the W vector) that Majewski found for his subdwarf sample in SA 57.

The determination of the rotation vector V for stars in the North Galactic Cap depends critically on selecting appropriate tracer halo stars and having accurate distances and proper motions. The recent availability of absolute proper motions (Spagna et al., 1996) based on the GSC-II catalogue (Lasker et al., 1995; McLean et al., 2000) affords a new opportunity to evaluate the rotation of the halo outside the Plane. This paper gives preliminary results from a limited sample.

2 The Data

2.1 Selection of halo stars

We used blue horizontal branch (BHB) stars and RR Lyrae stars as tracers. The former were selected from the surveys of Sanduleak (1988) and Pesch & Sanduleak (1989) and from the surveys of Beers et al. (1996). These candidate stars were confirmed by $uBV$-photometry (Kinman et al. 1994) and spectroscopy. Most of the confirming spectra of the BHB stars were taken at the Kitt Peak 4-m Mayall telescope (Kinman et al. 1996). RR Lyrae stars were selected from the GCVS (Kholopov 1985) and subsequent Name-Lists and also from Kinman (2002a). Intensity-weighted mean magnitudes of the RR Lyrae stars are derived from our recently observed light curves as these become available. A program to obtain spectra of the RR Lyrae stars at the 3.5-m TNG telescope is in process. Only 6 of these RR Lyrae stars and none of the BHB stars in our current sample

are included in the recent list of halo stars by Beers et al. (2000).

2.2 Absolute Magnitudes, Reddenings and Distances

The absolute magnitudes of RR Lyrae stars can be determined from their metallicity $[\text{Fe/H}]$ by a linear empirical relation of the form: $M_V = A[\text{Fe/H}] + B$. Chaboyer (1999) gives 0.23 and 0.93 while Cacciari (2002) gives 0.23 and 0.92 respectively for $A$ & $B$. These values are consistent with an LMC modulus of 18.50 and give $M_V$ which are in the middle of the range of recent $M_V$ determinations (Popowski & Gould 1999). $[\text{Fe/H}$, however, has still to be determined for most of our RR Lyrae sample, and so we used the relation based on the period (P) and Fourier coefficients (A1 and A3) given by Kovács & Walker (2001):

$$M_V = -1.876 \log P - 1.158A1 + 0.821A3 + \text{const.}$$

The constant was taken as 0.448 (Kinman 2002b) which gives $M_V$ close to the same scale as those derived from $[\text{Fe/H}]$. In the case of the BHB stars, we used the $M_V$ vs. $B - V$ relation given by Preston et al. (1991) adjusted so that $M_V = +0.60$ at $(B - V) = +0.20$. The reddening given by Schlegel et al. (1998) was adopted.

2.3 Proper Motions

We used proper motions that are based on the plate material used for the construction of the GSC-II catalogue (Spagna et al., 1996). The relative proper motions are transformed to an absolute reference frame by forcing the extended extragalactic sources to have null tangential motion. Since our results depend critically on the success of this transformation, it seemed desirable to test the GSC-II proper motions of a sample of QSO which have an image structure and colour similar to

the program stars. The area studied contains 51 objects that have GSC-II proper motions and that are listed as QSO brighter than 18th magnitude by Hewitt & Burbidge (1993, HB) and Véron-Cetty & Véron (2001, VV) in their catalogues. Six of these objects have surprisingly large (≥10 mas/yr) total proper motions and are listed in Table 3. Spectra of these objects were taken by Arjun Dey and Buell Jannuzi using the Kitt Peak 4.0-m telescope; their new classifications (private communication) are given in the final column of the Table. We note that VV rejected CSO 832 and CSO 823 from their catalogue citing Sanduleak & Pesch (1990) and Edwards et al. (1988) respectively. We therefore rejected the first five objects in Table 3 and assumed that the remaining 46 objects are all QSO which should have no proper motion. These 46 objects have the following mean GSC-II proper motion:

\[
\mu_\alpha = -0.646 \pm 0.357 \text{ mas/yr} \\
\mu_\delta = -0.300 \pm 0.507 \text{ mas/yr}
\]

These mean proper motions are an indication of the systematic errors that could be present in the GSC-II proper motions over a sky area and magnitude range similar to that of our program objects. In terms of the U and V velocity vectors at the North Galactic Pole, they correspond to:

\[
U = -1.8 \pm 1.9 \text{ km/s} \quad \text{and} \quad V = -2.9 \pm 2.2 \text{ km/s at 1 kpc}
\]
\[
U = -9.0 \pm 9.6 \text{ km/s} \quad \text{and} \quad V = -14.3 \pm 11.0 \text{ km/s at 5 kpc}
\]
\[
U = -18.0 \pm 19.2 \text{ km/s} \quad \text{and} \quad V = -28.6 \pm 22.0 \text{ km/s at 10 kpc}
\]

This suggests that the systematic error in the mean rotation (V) is probably no more than 25 km/s (1σ error) or at most 36 km/s (2σ error) for our program objects with a mean distance of about 5 to 6 kpc.

2.4 Results

Our complete sample consists of 87 confirmed BHB stars that have $b \geq 75^\circ$ (72 of which have $b \geq 80^\circ$). There are also 73 RR Lyrae stars in this area for which we are in the process of getting light curves and spectra. Our present results refer to a subset of 35 BHB stars (30 having radial velocities) and 18 RR Lyrae stars (of which 9 have radial velocities). In calculating the UVW vectors (Johnson 1987), we put the radial velocity equal to zero (with an error of ±150 km/s) if no radial velocity was available. In such cases, the U and V vectors should be very close to the correct values but the W velocity must be discarded. These heliocentric UVW are compared with those found by Martin & Morrison (1998) for their HALO2 sample of local RR Lyrae stars. They excluded disk RR Lyrae stars and trimmed 10% of the “outliers” from their sample. We have not attempted to remove disk stars from our sample ($Z > 1.6$ kpc) but found that trimming hardly changes the mean values of U, V and W although it does reduce the velocity dispersions $\sigma_u$, $\sigma_v$ and $\sigma_w$. Martin & Morrison used a $M_V$ that is less than 0.1 mag fainter than ours, but this should not account for the 60 km/s difference in V velocities (but very comparable $\sigma_v$). The 42 stars in our sample with $Z < 10$ kpc have almost the same $<V>$ ($−286±19$ km/s at $<Z> = 5.3$ kpc) as for the whole sample.

Gilmore et al. (2002) have recently reported retrograde halo rotation out of the Plane from their radial velocity determinations of stars at galactic longitude $270^\circ$. We shall determine UVW from our total sample at the North Galactic Pole in the near future, and hope to extend the work to halo stars in Anticentre fields. Possibly this will allow us to detect gradients in the V motion and discover whether this retrograde rotation is caused by local streaming or is part of a more widespread effect.
