When the bare cover of the endotherm is heat, then the surface, where
the bare cover of the endotherm, where the cover of the endotherm, then
(1) \( L + \theta = \Delta \theta \quad \theta = u = \Delta \)

Given the point, the cover of the endotherm is not exposed to the
endotherm, where the cover of the endotherm, where the cover of the endotherm, then
(2) \( L + \theta = \Delta \theta \quad \theta = u = \Delta \)

Therefore, the cover of the endotherm is not exposed to the
endotherm, where the cover of the endotherm, where the cover of the endotherm, then
(3) \( L + \theta = \Delta \theta \quad \theta = u = \Delta \)

When the bare cover of the endotherm is heat, then the surface, where
the bare cover of the endotherm, where the cover of the endotherm, then
(4) \( L + \theta = \Delta \theta \quad \theta = u = \Delta \)

When the bare cover of the endotherm is heat, then the surface, where
the bare cover of the endotherm, where the cover of the endotherm, then
(5) \( L + \theta = \Delta \theta \quad \theta = u = \Delta \)
dynamics depends only on one parameter $K$. Due to the discontinuity in $\theta$, the Kolmogorov-Arnold-Moser (KAM) theorem cannot be applied to the map and its dynamics becomes chaotic and diffusive for arbitrarily small values of the chaos parameter $K > 0$. For $K \ll 1$ the diffusion is governed by a nontrivial cantori regime which has been worked out in [8]. In this case the rescaled diffusion rate $D_\theta(K) = (\Delta y)^2/t \approx 12\pi^2 K^{5/3}$ is much smaller than the quasi-linear diffusion rate corresponding to the random phase approximation $D_\theta = \pi^2 K^{3/3}$ (the latter becomes valid only at $K \gg 1$). The diffusion rate in $n$ is $D = D_\theta(K)/T^2$.

To investigate the behavior of the concurrence in the quantum map, we compute $C$ for the two most significant qubits which determine the first two binary digits $a_{1,2}$ in the expansion of momentum $n$: the reduced density matrix $\rho$ for this qubit pair is obtained by tracing out all other $n_q = 2$ less significant qubits (the digits $a_i$ with $3 \leq i \leq n_q$ in the expansion of $n = (a_1 a_2 a_3 \ldots a_{n_q})$). After that $C$ is computed from $\rho$ as described in [8]. In this way we obtain the concurrence value $C$ on a global scale of the whole system which is decomposed into 4 equal parts with $N/4$ quantum states in each of them. In addition we fix $T = 2\pi L/N$ in the regime of quantum resonance so that $L$ gives the integer number of classical phase space cells embedded in the quantum torus of size $N$ [8]. The classical dynamics is periodic in $n$ with period $2\pi/T$. In the following we also take $L$ to be a multiple of 4 to have an integer number of classical cells in the 4 parts of the partition in the momentum $n$.

Typical examples of the dependence of $C$ on the number of map iterations $t$ are shown in Fig. 1. According to these data $C(t)$ decays exponentially down to a residual value $\bar{C}$ and, in the limit of large $N$, the decay rate $\gamma$ becomes independent of $N$. It is natural to compare this rate with the rate of classical relaxation. Indeed, due to underlying classical chaos, the probability distribution $f_n = [\psi_n]^2$ over $n$ is described by the Fokker-Planck equation $\partial f_n/\partial t = D\partial^2 f_n/\partial n^2/2$ which gives the relaxation to equipartition with the rate

$$\gamma_c = 2\pi^2 D/N^2 = D_\theta(K)/2L^2.$$  \hspace{2cm} (3)

The comparison between this classical value $\gamma_c$ and the rate of concurrence decay $\gamma$ is given in Fig. 2. It clearly shows that the decay rate of $C(t)$ is given by the classical rate: $\gamma = \gamma_c$. It is important to stress that this relation remains valid also in the nontrivial cantori regime ($K \ll 1$) and that the quantum decay reproduces all oscillations of the classical diffusion (see inset in Fig. 2).

The properties of the residual value of the concurrence $\bar{C}$ are analyzed in Fig. 3. For that we express $\bar{C}$ vs. the system conductance $g = 2\gamma_c/\Delta = N D_\theta(K)/L^2$ where, up to a constant factor, $\Delta = 1/N$ is the level spacing and $2\gamma_c$ is the Thouless energy (see a recent review [9]). In spite of strong fluctuations the data presented in Fig. 3 can be described by the global average dependence $\bar{C} \sim 1/\sqrt{g} \times 1/\sqrt{N}$. Indeed, for $K = 0.5$, $L = 4$ the system size varies by 3 orders of magnitude and the fit gives an algebraic decay with power $\alpha = 0.56 \pm 0.02$ being close to $1/2$. We attribute the presence of strong fluctuations to the fact that the value $\bar{C}$ is averaged only over time but there is no averaging over parameters. Thus, from the point of view of disordered systems $\bar{C}$ represents
FIG. 3: Dependence of the residual value of the concurrence $C$ on the system conductance $g = N \Delta_0(K)/L^2$ for a broad range of parameters; half filled circles show dependence on $L = 4, 8, 12, 16, 20$ for $K = 0.5$ and $n_s = 14, 15, 16$; diamonds and triangles show the variation with $K$ for $n_s = 14, L = 16$; $n_s = 15, L = 8$ and $n_s = 16, L = 4$. The filled circles connected by the dashed curve show the dependence on $N$ for $K = 0.5, L = 4$. The solid line marks the slope $1/\sqrt{N}$.

only one value for one realization of disorder.

We propose the following explanation of the results presented in Figs.1-3. For a state $|\psi\rangle$ like in Fig.1, we can write $|\psi\rangle = \sum_{a_1 a_2} |a_1 a_2\rangle |\phi_{a_1 a_2}\rangle$ where $a_{1,2} = 0$ or 1. Then the value of the concurrence $C$ is proportional to the difference of two scalar products, $C \sim |Q_{14} - Q_{23}|$, where $Q_{14} = 2\sqrt{\langle \phi_{00} | \phi_{11} \rangle^2}$ and $Q_{23} = 2\sqrt{\langle \phi_{01} | \phi_{10} \rangle^2}$. From this relation and the fact that the initial state is symmetrically distributed with respect to the transformation $n \to N - n$, it follows that $C$ is proportional to the difference $|W_{11} + W_{00} - W_{10} - W_{01}|$ where $W_{a_1 a_2}$ is the total probability inside the part $(a_1 a_2)$. In the classical limit this probability difference relaxes to zero with the classical relaxation rate $\gamma_c$, and that’s why $\gamma = \gamma_c$ in agreement with the data of Fig.2.

The residual value $C^*$ is determined by the quantum fluctuations of the previous difference of scalar products. In fact, due to the discretization of map $M$, the symmetry $n \to N - n$ is broken and $|\phi_{00}\rangle$ becomes different from $|\phi_{11}\rangle$. Therefore in the scalar product $Q_{14}$ (and $Q_{23}$) the $N/4$ terms have random signs and thus $Q_{14} \propto 1/\sqrt{N}$ (each term is of the order of $1/N$). In this estimate we assumed a summation over all $N$ wave function components. However for finite values of the conductance $g$ only the states inside the Thouless energy interval $2\gamma_c$ have a significant scalar overlap $Q_{14} \propto 1/\sqrt{N}$, and thus we can make a conjecture that $N$ should be replaced by the effective number of components which is of the order of $N_{\text{eff}} \sim \gamma_c/\Delta \sim g$. According to this, $C^* \sim 1/\sqrt{N}$ in agreement with the data of Fig.3.

The existence of a residual level of concurrence for an ideal quantum algorithm reflects the fact that the global behavior of the whole system remains coherent. In fact, the Poincaré theorem guarantees that for very large times the concurrence will have a revival close to the initial value (however, this will happen on an exponentially large time scale). The situation becomes qualitatively different in presence of external decoherence represented by noisy gates. In our numerical simulations, noisy gates are modeled by unitary rotations by an angle randomly fluctuating in the interval $(-\epsilon/2, \epsilon/2)$ around the perfect rotation angle. The presence of this external decoherence leads to a decrease of the residual value of $C$ as illustrated in Fig.4: the constant level is replaced by an exponential decay which gives $C \propto \exp(-\Gamma t)$.

In order to obtain the dependence of $\Gamma$ on the parameters we extracted it from the fit of the averaged ratio of $C$ under a noisy evolution to its value in the ideal one. An example of such ratio and the corresponding fit is shown in Fig.4. To suppress fluctuations we averaged over 20 realizations of the noisy evolution. Moreover, the fit was restricted to the plateau regime, where the exact concurrence is fluctuating around its residual value (the initial diffusive relaxation was excluded from the fit).

The results for $\Gamma$ obtained in this way are presented in Fig.5. Quite naturally we find that $\Gamma \propto \epsilon^2$, as it was also seen in other simulations of quantum algorithms with noisy gates (e.g. [21]). This scaling becomes better and better for large $\epsilon$ values where $\Gamma$ is larger. However, more surprisingly there is an exponential growth of $\Gamma$ with the number of qubits $n_q$ ($\Gamma \propto \sqrt{N}$). This result
FIG. 5: Dependence of the decoherence induced decay rate $\Gamma$ of the residual concurrence on $e^2\sqrt{N}$ for $K = 0.5$, $L = 4$. Here the noise amplitude $e$ changes from 0.001 to 0.01 (10 equidistant values) for $7 \leq n_q \leq 15$. The data points (circles) are connected by lines for fixed values of $e$. The color intensity changes gradually from one chain to another to mark the variation of $e$ (low/high intensity corresponds to small/large values of $e$). The straight line shows the averaged behavior $\Gamma = 0.58s^2\sqrt{N}$.

is very different from those obtained in [11, 12], where the time scale for fidelity and the decoherence rate for tunneling oscillations varied polynomially with $n_q$. We see two possible reasons for the exponential sensitivity of the residual concurrence to decoherence. At first, in our case $\Gamma$ is computed over a very large time interval, for which the quantum dynamics already reached its asymptotic behavior (plateau for the residual concurrence); it is known that on very large times the eigenstates are exponentially sensitive to imperfections due to the chaotic structure of the wave functions (see results and discussions in [21]). Another possible reason can be related to the fact that the residual value of the concurrence on the plateau is on its own exponentially small and maybe this is the reason why it becomes so sensitive to decoherence. Further investigation on the decoherence effects for the concurrence are required to understand in a better way this exponential sensitivity of $C$.

In summary, our studies show that the decay of the concurrence in an operating quantum computer is determined by the underlying relaxation rate of the classical dynamics. We show that the residual level of entanglement in an ideal algorithm scales as the inverse square root of the conductance of the system. This residual entanglement is destroyed by decoherence, whose effective rate grows exponentially with the number of qubits.

[4] namely, $S$ monotonically increases from 0 to 1 when $C$ goes from 0 to 1, i.e., $\Gamma = 0.58s^2\sqrt{N}$.
