Spectral Properties of the
Overlap Dirac Operator in QCD

We discuss the eigenvalue distribution of the overlap Dirac operator in quenched QCD on lattices of size $8^4$, $10^4$ and $12^4$ at $\beta = 5.85$ and $\beta = 6$. We distinguish the topological sectors and study the distributions of the leading non-zero eigenvalues, which are stereographically mapped onto the imaginary axis. Thus they can be compared to the predictions of random matrix theory applied to the $\epsilon$-expansion of chiral perturbation theory. We find a satisfactory agreement, if the physical volume exceeds about $(1.2 \text{ fm})^4$. For the unfolded level spacing distribution we find an accurate agreement with the random matrix conjecture on all volumes that we considered.
1 Introduction

_Chiral perturbation theory_ is a powerful tool to analyze QCD at low energy. In this context, the pions as the lightest hadrons carry the relevant degrees of freedom. They are considered as quasi-Nambu-Goldstone bosons obtained from chiral symmetry breaking — their mass is provided by the masses of the $u$ and $d$ quark, which are small compared to $\Lambda_{QCD}$. One then constructs an effective theory for the expansion in the pion mass and momenta, which is strongly constrained by the requirements of chiral symmetry.

In particular the so-called $\epsilon$-expansion is designed to describe the system in a volume which is so small that it cannot even include a pion Compton wavelength [1]. In this situation the role of the topological sectors of the gauge field is far more important than it is the case in a large volume [2].

In view of the comparison to lattice data, it is an important virtue that a finite and even small volume can be interpreted directly — in contrast to most other lattice simulations one does not need to extrapolate to large volumes. Chiral perturbation theory in the $\epsilon$-expansion describes the finite volume and quark mass dependence of various quantities such as the scalar condensate or 2-point correlation functions. These dependencies are parametrized by the same low energy constants as in the effective chiral Lagrangian in the infinite volume. Therefore the unphysical small volume can provide results for physical parameters. The finite size effects allow for a determination of the low energy constants in the effective chiral Lagrangian. Examples of this procedure are given in Ref. [3] for the $O(4)$ symmetric non-linear $\sigma$-model, and in Ref. [4] for (quenched) QCD.

In this paper we are going to investigate _Ginsparg-Wilson fermions_ [5, 6], which allow for simulations at small fermion masses. In particular, the evaluation of the corresponding lattice Dirac operator can be done directly in the chiral limit, where the Ginsparg-Wilson fermion has an exact (lattice modified) chiral symmetry at finite lattice spacing [7]. Moreover, since the Ginsparg-Wilson fermions have exact zero modes, we can use them to define the topological charge of the lattice gauge field [6, 7] by means of the Atiyah-Singer Index Theorem [8].

A particularly simple solution of the Ginsparg-Wilson relation is obtained if the Wilson operator is inserted into the overlap formula [9]. As long as the gauge coupling is not too strong, such a lattice Dirac operator is local [10] in the sense of an exponential localization, hence it is conceptually correct.
in view of the continuum limit. However, its simulation is tedious: for the
time being, only quenched QCD simulations are feasible. Since also the
quenched chiral perturbation theory in the $\epsilon$-regime has been analyzed [11],
the simulation data can be compared to these analytical predictions.

Even without considering hadrons, there are interesting predictions for
the spectrum of the Dirac operator which are based on Random Matrix The-
ory (RMT), following the ideas of Ref. [2]. Chiral RMT simplifies QCD to a
Gaussian distribution of the elements in the fermion matrix, with the global
symmetries of the QCD Dirac operator. For a review on this field, see for
instance Ref. [12]. We only mention that although on the Lagrangian level
RMT is equivalent to chiral perturbation theory at lowest order in the $\epsilon$-
expansion, the predictions for the eigenvalue distributions involve additional
assumptions. Thus numerical simulations can provide a test of the predic-
tions from RMT beyond chiral perturbation theory. Even if the fermion
mass vanishes, there is still a lower limit for the volume where RMT applies;
in some steps, the latter assumes the volume (mathematically) to be infi-
nite. Theoretically one often requires the temperature $T$ to be well below
the Thouless energy $T \ll E_c = F^2_\pi/(\sqrt{\Sigma})$. However, it is not predicted
explicitly at which lower bound for the volume RMT really collapses.

There are explicit predictions for the statistical distribution of the low-
lying eigenvalues [13, 14] which can be confronted with lattice data. We
refer here to predictions in full QCD, although one might be worried that
quenching causes logarithmic corrections [15]. In this comparison, the chiral
condensate $\Sigma$ enters as a free parameter, hence, in turn, the fit to the
functions predicted by RMT provide a value for $\Sigma$. Another theoretical con-
jecture refers to the unfolded level spacing distribution which is not sensitive
to the energy scale, but which allows for the inclusion of bulk eigenvalues.

Such studies were performed before, using staggered fermions in QCD
[16], as well as Ginsparg-Wilson fermions in the Schwinger model [17], in
QED [18] and in QCD on $4^4$ lattices [19, 20]. Here we are going to present
data for the overlap Dirac operator spectrum in quenched QCD on larger
lattices than used before for Ginsparg-Wilson fermions.
2 The spectrum of the overlap Dirac operator compared to the RMT predictions

2.1 Theoretical aspects

In QCD with two massless quark flavors, the chiral symmetry breaks spontaneously as

$$SU(2)_L \otimes SU(2)_R \rightarrow SU(2)_{L+R},$$  \hspace{1cm} (2.1)$$

which generates three Nambu-Goldstone bosons. If we deal with light $u$ and $d$ quarks, these bosons pick up small masses because the quark mass breaks the chiral symmetry explicitly. The resulting quasi-Nambu-Goldstone bosons are identified with the pions. They can be represented by $SU(2)$ matrix fields $U_\mu(x)$. At low energy they are effectively described by chiral perturbation theory. To the leading order, the corresponding Lagrangian reads

$$\mathcal{L}[U] = \frac{F_\pi^2}{4} \text{Tr} \left[ \partial_\mu U(x) \partial^\mu U^\dagger(x) \right] - \frac{\Sigma m}{2} \text{Tr} \left[ e^{i\theta/2} U(x) + e^{-i\theta/2} U^\dagger(x) \right].$$  \hspace{1cm} (2.2)$$

Here $m$ is the quark mass (for simplicity we assume it to coincide for the two flavors) and $\theta$ is the vacuum angle. The coupling constants in leading order are the pion decay constant $F_\pi$ and the chiral condensate $\Sigma$.

We put the system in a periodic box of size $L^4$. Then the $\epsilon$-regime is characterized by the condition

$$\frac{1}{m_\pi} \gg L \gg \frac{1}{4\pi F_\pi}, \quad m_\pi = \text{pion mass}.$$  \hspace{1cm} (2.3)$$

In this regime, RMT can be applied to the Dirac operator $D$. In the continuum it leads to explicit formulae for the statistical distribution of the low eigenvalues, i.e. for the “microscopic regime”. There the momenta are counted as $O(1/L)$. One introduces the spectral density

$$\rho(\lambda) = \langle \sum_n \delta(\lambda - \lambda_n) \rangle,$$  \hspace{1cm} (2.4)$$

where the sum runs over all modes, and $\lambda_n$ are the eigenvalues of the operator $iD$. It is favorable to use the dimensionless variable

$$z = \lambda V \Sigma,$$  \hspace{1cm} (2.5)$$
which is of $O(1)$. In these terms, the RMT prediction addresses the microscopic spectral density

$$
\rho_s(z) = \lim_{V \to \infty} \frac{1}{V \Sigma} \rho(z/V \Sigma),
$$

(2.6)

which can be decomposed into the contributions of different topological sectors,

$$
\rho_s(z) = \sum_{\nu = -\infty}^{\infty} \rho_{s}^{(\nu)}(z), \quad \nu = \text{topological charge}.
$$

(2.7)

Refs. [14] present expressions for the leading contributions $\rho_{n}^{(\nu)}(z)$ in

$$
\rho_s^{(\nu)}(z) = \sum_n \rho_{n}^{(\nu)}(z),
$$

(2.8)

where the sum runs over the non-zero modes. The predictions for the lowest eigenvalue at $|\nu| = 0, 1$ and $2$ are depicted in Figure 1. We see in particular that the density peak moves to larger values of $z$ as $|\nu|$ increases.

![Figure 1](image.png)

**Figure 1:** The distributions for the lowest eigenvalue at $|\nu| = 0, 1$ and $2$, as predicted by chiral RMT.
2.2 Lattice results in the microscopic regime

In order to verify the viability of the $\epsilon$-expansion and of chiral RMT, it is of interest to compare these predictions to the corresponding eigenvalue distributions obtained from lattice simulations. The Wilson Dirac operator seems hardly suitable in this respect; because of the mass renormalization it would be highly problematic to identify the zero modes and the relative values of the remaining modes. In addition, simulations at small quark masses are problematic due to exceptional configurations.

Staggered fermions do not suffer from additive mass renormalization because they have an exact remnant chiral symmetry $U(1) \otimes U(1)$. Indeed such comparisons exist. The staggered fermion spectrum agrees well with the RMT prediction in the sector $\nu = 0$. However, it turns out that all other sectors, $\nu \neq 0$, yield the same distributions, in particular the same histogram for $\rho_1^{(\nu)}(z)$ in QCD [16]. It seems that staggered fermions are generally insensitive to the topology, and therefore not adequate for this purpose.

Another type of lattice fermions without additive mass renormalization is the Ginsparg-Wilson fermions. Their lattice Dirac operator $D$ fulfills the Ginsparg-Wilson relation (GWR), which reads (in its simplest form)

$$D\gamma_5 + \gamma_5 D = \frac{a}{\mu} D\gamma_5 D ,$$

(2.9)
i.e. the continuum condition for the right-hand-side to vanish is relaxed to a term of $O(a)$, where $a$ is the lattice spacing. $\mu$ is a mass parameter, see below. The GWR implies that $D^{-1}\gamma_5 + \gamma_5 D^{-1} = a\gamma_5/\mu$ is local, therefore the poles in the propagator are not shifted away from zero. Thus the Ginsparg-Wilson fermions have exact zero modes, which occur with positive or negative chirality. We now define the topological charge $\nu$ simply by the index

$$\nu = n_+ - n_- ,$$

(2.10)
where $n_+$ ($n_-$) is the number of positive (negative) chiral zero modes. Here one adapts the continuum Index Theorem and uses it to define the topological charge of the lattice gauge configurations [6, 7]. The applicability of chiral RMT to Ginsparg-Wilson fermions has been discussed theoretically in Ref. [21].
Many lattice Dirac operators, such as the Wilson operator $D_W$, obey $\gamma_5$ Hermiticity, $D_W^\dagger = \gamma_5 D_W \gamma_5$. This allows for a simple solution of the GWR by inserting $D_W$ (say with Wilson parameter 1) into the overlap formula \[9\],

$$D_{ov} = \frac{\mu}{a} \left[ 1 + A/\sqrt{A^\dagger A} \right], \quad A = aD_W - \mu. \quad (2.11)$$

$D_{ov}$ is a solution to condition (2.9) and it is $\gamma_5$-Hermitian as well. (There are alternatives to replace $D_W$ by lattice Dirac operators that are more involved but lead to improved properties, as suggested in Refs. \[22\].) $\mu$ represents a negative mass of the Wilson fermion, which can be chosen in some interval as long as the gauge fields are smooth. In the free case $\mu = 1$ is optimal with respect to locality, but at $\beta = 6$ and $\beta = 5.85$ we move to $\mu = 1.4$ resp. $\mu = 1.6$ to compensate the mass renormalization of the Wilson fermion.

Note that the operator $A/\sqrt{A^\dagger A}$ is unitary, hence the spectrum of $D_{ov}$ is located on a circle in the complex plane through zero, with center and radius $\mu/a$. In order to relate the eigenvalues found on this Ginsparg-Wilson circle to the continuum eigenvalues $\lambda_n$, we map the circle stereographically onto the imaginary axis. Requiring $f(z) = z + O(z^2)$ and $f(2\mu) = \infty$ singles out the Möbius transform

$$f(z) = \frac{z}{1 - z/(2\mu)}. \quad (2.12)$$

This mapping has been suggested before in Ref. \[23\], in connection with the Leutwyler-Smilga sum rules \[2\].

The eigenvalues of Ginsparg-Wilson operators were compared to the RMT prediction for the Schwinger model in Ref. \[17\], where the overlap operator (2.11) as well as a truncated fixed point Dirac operator were considered. In both cases the results agreed with the RMT formulae.

Such studies were also performed with the overlap operator in 4d QED \[18\] and again the predictions were successful within the statistical errors.

Finally QCD was considered, but only on small lattices of size $4^4$. Ref. \[19\] used the overlap operator at strong coupling of $\beta = 5.1$. Ref. \[20\] applied a truncated fixed point action and obtained a decent agreement in a volume of $V = (1.2 \text{ fm})^4$. However, when the physical lattice spacing is decreased so that the volume shrinks to $(0.88 \text{ fm})^4$, the leading non-zero eigenvalue distributions of the different topological sectors are on top of each other, in
contrast to the RMT prediction.

Our results are obtained by using again the overlap operator (2.11) in QCD with the standard plaquette gauge action. We have chosen a rather weak gauge coupling, \( \beta \geq 5.85 \), so that the overlap formula can safely be applied to construct a Ginsparg-Wilson fermion \(^1\). Due to the computational effort required by the overlap operator we had to use the quenched approximation, as it was also the case in all previous studies mentioned above. We approximated the inverse square root by Chebyshev polynomials to an accuracy of \( 10^{-12} \). Then we used the PARPACK routines to evaluate up to 100 eigenvalues of \( D_{\text{ov}} \). We focused on the eigenvalues with the least real parts resp. absolute values. Of course the non-zero eigenvalues occur in complex conjugate pairs, hence we only consider one sign for the imaginary part.

First we measured the leading non-zero eigenvalue on a \( 12^4 \) lattice at \( \beta = 6 \). Here the volume amounts to \((1.12 \text{ fm})^4\). The result can be represented by a histogram, which could then be compared to Figure 1. However, such a picture depends on the (arbitrary) choice of the bin size in the histogram. This can be avoided by plotting the “cumulative density”, see e.g. Ref. [25], which sums up all the entries up to the considered value of \( z \) — it is normalized so that the full number of entries corresponds to the cumulative density 1. This way to plot the data can be compared to the cumulative density according to the RMT prediction,

\[
\rho^{(\nu)}_{1,c}(z) = \frac{\int_0^z \rho^{(\nu)}(z')dz'}{\int_0^\infty \rho^{(\nu)}(z')dz'}. \tag{2.13}
\]

This comparison is done in Figure 2 (top). We recognize a satisfactory agreement, especially for \(|\nu| = 1\), where we have the largest statistics, see Table 1. In particular, we do see the effect that the peak of the density — resp. the interval of steepest ascent of the cumulative density — moves to larger values of \( z \) for increasing topological charge. In this plot the chiral condensate \( \Sigma \)

\(^1\)From our point of view, it is not clear if the overlap fermion is well-controlled at stronger coupling. For instance, typical spectra at \( \beta = 5 \) and even \( \beta = 5.4 \) on \( 4^4 \) lattices have their eigenvalues spread over a broad area [24], so that it is hardly possible to find a good value for \( \mu \) which would split the (nearly) real eigenvalues into a small branch (to be mapped to the vicinity of 0), and a large branch (to be mapped onto the opposite arc of the Ginsparg-Wilson circle).
enters as the one free parameter, which sets the energy scale. Our plot is shown for the value
\[ \Sigma = (256 \text{ MeV})^3, \] (2.14)
which provides optimal agreement with the RMT curves.

Next we studied a $10^4$ lattice at $\beta = 5.85$, which corresponds to a slightly larger physical volume of $V = (1.23 \text{ fm})^4$. Again the results for the leading non-zero eigenvalue are shown for the topological sectors $|\nu| = 0, 1$ and 2 in Figure 2 (bottom). Also here we find a reasonable agreement with the RMT predictions, but the optimal value of the chiral condensate is modified to $\Sigma = (253 \text{ MeV})^3$. RMT predicts a (logarithmically) increasing $\Sigma(V)$ due to quenching [15]. A conclusive verification of this behavior (beyond possible lattice artifacts) would require further simulations.

In Figure 3 we show our results for the cumulative density of the next-to-leading eigenvalue at $\nu = 0$, for both lattices discussed before. We find a good agreement with the RMT prediction in the first Ref. of [14], again in particular for the $L = 10$ lattice, which corresponds to a larger physical volume. We also show the data for $|\nu| = 1$ and 2, which agree well for $L = 10$ and $L = 12$. Also the second non-zero eigenvalue moves to larger values of $z$ if $|\nu|$ increases.

Now we consider the eigenvalue density without focusing particularly on the first or on the second non-zero eigenvalue (though we still omit the zeros). Then we obtain for instance at $|\nu| = 1$ the densities shown in Figure 4. RMT predicts an oscillating behavior (see first Ref. in [13]), which is also plotted for comparison. We find a good agreement roughly up to the second peak (as expected from Figures 2 and 3). Then we are leaving the microscopic regime and turn to the bulk; for the latter the density is supposed to rise as $\lambda^3$ resp. $z^3$. This is nicely confirmed by our data; an example is illustrated in Figure 5.

Finally we consider a smaller volume: we use a $8^4$ lattice at $\beta = 5.85$, which corresponds to $V = (0.98 \text{ fm})^4$. Figure 6 shows that in this case there is a clear disagreement with the RMT prediction; in particular the sensitivity of the peak to $|\nu|$ is lost to a large extent (beyond very small values of $z$). This is in qualitative agreement with the results of Ref. [20] on the $4^4$ lattice. The observation that the volume has to be $V \succ (1.2 \text{ fm})^4$ can be viewed as an empirical determination of the Thouless energy.

At this point, we would like to add that the above results tend to look
similar for the leading eigenvalues of the Hermitian overlap Dirac operator
\[ H_{ov} = \gamma_5 D_{ov} \, . \] (2.15)

(Of course, in this case the stereographic mapping is not needed.) As an example we show the cumulative density of the first positive (non-zero) eigenvalue of \( H_{ov} \) at \( L = 10, \beta = 5.85 \) in Figure 7.

For completeness we report our statistics in Table 1 and summarize the results in Table 2. In that Table we also include an estimate for the topological susceptibility, where some configurations with higher charges contribute as well. We present the dimensionless quantity \( \chi_t r_0^4 \), where \( \chi_t = \langle \nu^2 \rangle / V \) is the susceptibility and \( r_0 \) is the Sommer parameter obtained from the static quark-antiquark potential [26]. The results are well consistent with the values in the literature (for an overview, see Ref. [20], Fig. 18) although our statistics is clearly too small for that quantity. (Hence we do not try to estimate errors on \( \Sigma \) and \( \chi_t r_0^4 \).) Finally Table 2 also gives the results of the Kolmogorov-Smirnov test [25] for the confidence level of the results obtained, if one assumes the RMT probability distribution to be correct. The corresponding number described the probability for the observed deviation from the theory to occur with the given statistics. This test is just designed for the cumulative density. The results suggest that the volume \((1.12 \text{ fm})^4\) is still somewhat small, so that the topologies are still not fully separated, but we see that this process sets in on volumes larger than that.

### 2.3 Unfolded distribution

We now turn to another way of comparing our lattice data to a conjecture from RMT. This new evaluation allows us to take all our non-zero eigenval-

| lattice size | \( \beta \) | physical volume | number of configurations | \( \nu = 0 \) | \( |\nu| = 1 \) | \( |\nu| = 2 \) |
|--------------|----------|-----------------|------------------------|---------|---------|---------|
| \(12^4\)     | 6        | \((1.12 \text{ fm})^4\) | 44                     | 70      | 24      |
| \(10^4\)     | 5.85     | \((1.23 \text{ fm})^4\) | 68                     | 99      | 69      |
| \(8^4\)      | 5.85     | \((0.98 \text{ fm})^4\) | 66                     | 53      | 26      |

Table 1: The statistics of our simulations on three lattice sizes.
Table 2: The results on the two lattices which turned out to be sufficiently large for the data to be compared with the RMT predictions, for the suitable values of $\Sigma$ used in Figure 2. We also display the statistical confidence level according to the Kolmogorov-Smirnov test, and our results for the topological susceptibility $\chi_t$ ($r_0$ is the Sommer parameter).

for the condensate or the pion decay constant. Nevertheless, the unfolded
distribution provides a non-trivial test for RMT.

3 Conclusion

We performed a lattice study of quenched QCD using the overlap operator
to test RMT predictions for the eigenvalue distributions of the Dirac operator.
In this pilot study we worked at $\beta$ values large enough so that the overlap
formula can safely be applied as a solution of the GWR. By using lattices of
size $8^4, 10^4$ and $12^4$ we were able to reach physical volumes which are large
enough to test RMT.

In the microscopic regime of the very small eigenvalues we observe agree-
ment with the predictions by RMT applied to the $\epsilon$-regime of chiral perturba-
tion theory, if the physical volume is large enough; $V \gtrsim (1.2 \text{ fm})^4$ seems to be
sufficient. On smaller physical volumes this agreement — and in particular
the sensitivity to the topology — disappears.

If we consider the unfolded level spacing distribution, however, we obtain
a good agreement with the RMT conjecture, even down to a small physical
volume.

The eigenvalue distributions in Figure 2 show interesting characteristic
features. In topological charge sector zero the probability for a very low non-
zero eigenvalue is non-negligible. Therefore such very low-lying modes will
appear in simulations. This might have serious consequences for numerical
studies when the quark mass is lowered too much. In particular, this behavior
might render simulations in the $\epsilon$-regime problematic. Indications of these
difficulties were presented in Ref. [4], where also an analysis of the influence
of the lowest mode in the $\nu = 0$ sector on the measurement of the chiral
condensate was given. It was reported that the condensate is very hard
to measure in topological charge sector zero, in agreement with the results
presented here.

On the other hand, the situation is clearly better in a non-trivial topology.
Eigenvalues close to zero are strongly suppressed and a much better signal
can be expected.

Note that this phenomenon is not restricted to the quenched approxi-
mation considered here but holds also in the full theory. Thus, it can be
expected that simulations close to physical values of the pion mass may be-
come extremely expensive. Clearly, contact to chiral perturbation theory is then mandatory to extrapolate to physical pion masses.

### 3.1 Outlook

We still want to proceed to larger physical volumes. This will hopefully lead to further precision in the agreement for the leading non-zero eigenvalues in the different topological sectors. The larger volume might provide a histogram for the spectral density, which follows the microscopic RMT for several oscillations. With an increased statistics — which may be accessible using the optimized algorithmic techniques described in Ref. [28] — we could evaluate the spectral correlators as well. Further values for $\Sigma(V)$ would also allow us to extract an estimation for $F_\pi$ [15]. Finally we are also about to extend this analysis to a hypercube overlap fermion, which is described in Ref. [29]. This is a different Ginsparg-Wilson fermion, and its study will provide a more complete picture of the spectral behavior of this class of lattice Dirac operators.

Figure 2: The cumulative distribution of the lowest non-zero eigenvalue at $\beta = 6$ on a $12^4$ lattice (top), and on a $10^4$ lattice at $\beta = 5.85$ (bottom). We show the RMT predictions (lines) and result for the indices $|\nu| = 0, 1, 2$. In both cases, in particular at $L = 10$, we find a satisfactory agreement with RMT, if the chiral condensate is chosen optimally. This requires $\Sigma = (256\text{MeV})^3$ (top) and to $\Sigma = (253\text{MeV})^3$ (bottom). The $10^4$ lattice corresponds to a slightly larger physical volume.
Figure 3: The cumulative density of the second non-zero eigenvalue at $L = 12$, $\beta = 6$ and at $L = 10$, $\beta = 5.85$. In both cases we find a good agreement with the RMT prediction (solid line). We also include the data for $|\nu| = 1$ and 2, which agree well for the two lattices. Also the second eigenvalue moves to larger values for increasing $|\nu|$. 
Figure 4: The density of eigenvalues of the Dirac operator in the microscopic regime, for the 12^4 lattice at $\beta = 6$ (top) and for the 10^4 lattice at $\beta = 5.85$ (bottom). In both cases, we show as an example the data for $|\nu| = 1$, which follow the RMT predicted oscillating behavior (dashed line) roughly up to the second peak. If the oscillation is averaged to a plateau, its height agrees with the eigenvalue density at zero according to the Banks-Casher relation, $\rho(z = 0) = \rho(\lambda = 0)/\Sigma V = 1/\pi$. 
Figure 5: The eigenvalue density on the $12^4$ lattice at $\beta = 6$, $|\nu| = 1$. We see the transition from the microscopic regime to the bulk, where the density follows the predicted increase $c_0 + c_1 \lambda^3$ (dashed line).
Figure 6: The cumulative density of the lowest non-zero eigenvalue at $\beta = 5.85$ on a $8^4$ lattice. The data from different topological sectors are close to each other (beyond very small $z$ values), hence in this small volume they do not agree with the RMT curves.

Figure 7: The cumulative density of the lowest non-zero eigenvalue of the Hermitian overlap Dirac operator $H_{ov} = \gamma_5 D_{ov}$ on the $10^4$ lattice at $\beta = 5.85$. 
Figure 8: The unfolded level spacing distribution for $\beta = 6$ on a $12^4$ lattice (top), and for $\beta = 5.85$ on a $8^4$ lattice (bottom). We find a convincing agreement with the RMT conjecture for the $SU(3)$ group in the fundamental representation that we are using. The same also holds for the $10^4$ lattice at $\beta = 5.85$. (The curves are normalized according to the number of entries in the statistics.)
