Abstract

We numerically investigate dynamical and chemical properties of star clusters (open and globular clusters, and “super star clusters”, SSC) formed in interacting/merging galaxies. The investigation is two-fold: (1) large-scale (100pc-100kpc) SPH simulations on density and temperature evolution of gas in interacting/merging galaxies and (2) small-scale ones on the effects of high gas pressure of ISM on the evolution of molecular clouds. We find that the pressure of ISM in merging galaxies can become higher than the internal pressure of GMCs (∼10 5 k B K cm −3), in particular, in the tidal tails or the central regions of mergers. We also find that GMCs can collapse to form super star clusters within an order of 10 7 yr owing to the strong compression by the high pressure ISM in mergers. Keywords: Galaxy: kinematics and dynamics

1 Introduction

Star clusters (hereafter SC) such as open, globular, and super-star clusters are observed to be relatively “minor” components (in mass) in luminous galaxies (e.g., the mass ratio of the Galactic GCs to the Galactic luminous disk mass is an order of 0.1 %). Therefore, it is generally considered that dynamical evolution of star clusters (e.g., merging or tidal destruction of star clusters) does not influence significantly the evolution of luminous galaxies. However, recent numerical simulations on dynamical evolution of SCs have strongly suggested that this SC dynamics is very important for the formation of galactic nuclei in dwarf irregulars/ellipticals and that of ultra-compact dwarf galaxies (Drinkwater et al. 2003), because (1) time scale of dynamical friction of SCs is relatively short (∼10 7 yr) and (2) cross section of SC merging is also large owing to the larger S N of dwarf galaxies (Bekki et al. 2003). Furthermore recent HST observations have revealed a significant number of young super star clusters (hereafter SSC) in dwarf irregular galaxies and suggested that physical properties of these SSCs can be correlated with those of their host galaxies (e.g., Billett et al. 2002). These recent numerical and observational results lead the author to investigate (1) how SSCs can be formed in galaxies, (2) how these SSCs dynamically evolve, and (3) whether or not there can be a strong physical relationship between structural and chemical properties of SSCs and those of their host galaxies. In this paper, we discuss these problems based on numerical simulations of SSC formation in galaxies. We here focus on SSC formation in major mergers, because recent HST observations discovered many SSCs in interacting/merging galaxies (e.g., Whitmore et al. 1993).

2 A new two-fold numerical model

Since it is very hard to resolve SSC formation sites (less than pc) and investigate the formation processes in detail in large-scale (10-100kpc) galaxy simulations, we adopt the following novel two-fold method for the numerical investigation of SSC formation. Firstly, we investigate time evolution of pressure, temperature, and density of warm interstellar medium (ISM) with the initial temperature of ∼10 4 K and the density of 1 atom cm −3, based on galaxy-scale (larger-scale) SPH simulations on galaxy mergers with total particle number (N) of ∼10 5. Secondly, we investigate dynamical evolution and star formation histories of GMCs embedded by hot (warm), high pressure ISM, based on GMC-scale (<100pc) SPH simulations (N ∼4 × 10 4). Primary focus here is to investigate how the high pressure ISM (expected for galaxy mergers) trigger collapse of GMCs and consequently form SSCs within the GMCs. In the second simulations, the data of the ISM surrounding GMCs come from the first simulations: The present simulations are fully self-consistent and mimic (or corresponds to) the simulations with N ∼10 4.

2.1 Galaxy-scale

Our numerical methods for modeling chemodynamical evolution of galaxy mergers have already been described by Bekki & Couch (2001) and the details of the adopted TREESPH are given by Bekki (1995). We accordingly give only a brief review of them here. We construct models of galaxy mergers between gas-rich disks by using the model of Fall-Efstathiou (1980). The total mass and the size of a progenitor exponential disk are M d and R d, respectively. From now on, all the masses and lengths are measured in units of M d and R d, respectively, unless otherwise specified. Velocity and time are measured in units of v = (GM d /R d) 1/2 and t dyn = (R d /GM d ) 1/2, respectively, where G is the gravitational constant and assumed to be 1.0 in the present study. If we adopt M d = 6.0 × 10 10 M ⊙ and R d = 17.5 kpc as fiducial values, then v = 1.21 × 10 2 km s −1 and t dyn = 1.41 × 10 8 yr, respectively. The dark-to-disk halo mass ratio and the star-to-gas mass ratio are set equal to 4.0 and 9.0, respectively. Bulge component is not included in the present study. An isothermal equation of state is used for the gas with a temperature of 7.3 × 10 3 K (corresponding to a sound speed of 10 km s −1). We present the results mostly for merger models with nearly prograde-prograde orbital configurations, parabolic encounters, and a pericentric distance of 0.5 R d.
2.2 GMC-scale

We numerically investigate the hydrodynamical effects of the high pressure ISM on a self-gravitating molecular gas cloud in major mergers. The cloud is represented by 20,000 SPH particles and the initial cloud mass \( M_{\text{cl}} \) and size \( r_{\text{cl}} \) are set to be \( 10^6 M_\odot \) and 97 pc, respectively, which are consistent with the mass-size relation observed by Larson (1981). The cloud is assumed to have an isothermal radial density profile with \( \rho(r) \propto 1/(r + a)^2 \), where \( a \) is the core radius of the cloud and set to be 0.2 \( r_{\text{cl}} \). An isothermal equation of state with a sound speed of \( c_s \) is used for the gas, and \( c_s \) is set to be 4 km s\(^{-1}\) (consistent with the prediction from the virial theorem) for models with \( M_{\text{cl}} = 10^6 M_\odot \). Each SPH particle is also subject to the hydrodynamical force of the ISM whose strength depends on the parameters of the ISM. The ISM is represented by \( \sim 20000 \) SPH particles and an isothermal equation of state with pressure \( p \) (or sound velocity of \( c_h \)), and density, \( \rho \). The ISM particles are uniformly distributed within a box with size of \( 6R_{\text{cl}} \). A gas particle in a cloud is converted into a collisionless stellar particle if (1) the local dynamical time scale [corresponding to \( (4\pi G\rho)/0.5 \), where \( G \) and \( \rho \) are the gravitational constant and the density of the gas particle, respectively] is shorter than the sound crossing time (corresponding to \( h_i/c_s \), where \( h_i \) is the smoothing length of the gas), and (2) the gaseous flow is converging. This method thus mimics star formation due to Jeans instability in gas clouds. In the model without ISM effects, star formation does not occur at all in this star formation method. We mainly show the result of the “fiducial model” with \( \rho = 1 \) atom cm\(^{-3}\) and \( P = 10^5 \) kB \( \text{cm}^{-3} \), because this model shows the typical behavior of ISM-induced star formation in a gas cloud.

3 Result I. SSC formation sites.

Figure 1 clearly demonstrates how the gaseous pressure of the interstellar medium becomes dramatically higher (\( 10^4 - 10^5 \) kB) in some regions of the major merger model at \( T = 0.28 \) Gyr (starburst phase with the star formation rate of \( \sim 75 M_\odot \) yr\(^{-1}\)) in comparison with the initial disks. Furthermore, gaseous pressure for some fraction of the gas particles (in particular, in the central regions) exceeds the threshold value of \( 2.0 \times 10^5 \) kB for SSC formation, essentially because rapid transfer of gas to the central region of the merger and efficient gaseous shock dissipation increase the gaseous density and pressure greatly. These results clearly explain the reason why SSCs can be formed in starbursting galaxies and imply that the formation efficiency of SSCs are much higher in merging galaxies with massive starbursts than in “normal” disk galaxies. Figure 1 also shows that SSCs are formed not only in the central region, where gas fueling is more efficient, but also in the outer tidal tails and “bridges” among the two cores, where the tidal force of the merger forms thin and high-density gaseous layers owing to gaseous shock dissipation (More details are given in Bekki & Couch 2001).

4 Result II. Implosive SSC formation.

Figures 2 and 3 describe how a burst of star formation within a gas cloud can be triggered by the external gas pres-
Star clusters

Figure 2: Time evolution of a GMC embedded by high pressure ISM for gaseous components (cyan) and for new stars formed from the gas (magenta). One frame measures 200 pc on a side. Note that a very compact SSC is formed owing to strong external compression of the GMC by the hot, high pressure ISM.

Figure 3: Time evolution of star formation rate of the model in Figure 2. Note that the time scale of starburst is less than a few Myr, which is shorter than the lifetime of very massive stars. This implies that supernovae feedback effects are less likely to influence super star cluster formation.

Figure 4: Final projected surface density distribution of a SSC developed in the model in Figure 2 (in our units). Since the system has not yet relaxed dynamically just after the formation of the SSC, the density profile shows a hollow around log (R) = -1.7.
5 Conclusions.

We first demonstrated that SSCs can be formed from GMCs “in an implosive manner” for major mergers: Strong external pressure of ISM in mergers can trigger the collapse of GMCs and consequently cause the rapid star formation within the GMCs. The star formation efficiency in the GMCs under strong external pressure is as high as 60 – 80% (in total cloud mass) so that the developed SSCs can be considered to be bound star clusters (e.g., Hills 1980). The present study suggests that unbound star clusters that are doomed to be destroyed by some external processes (e.g., galactic tidal field and interaction with GMC) can be formed from GMCs embedded by low (normal) pressure ISM whereas SSCs can be formed from GMCs embedded by very high pressure ISM. The stars initially within unbound star clusters could soon be identified as “field stars” after the destruction of the clusters. The time scale of SSC formation is very short (a few times $10^6$ yr, which is shorter than the lifetime of very massive stars, which are responsible for the type II supernovae) so that the energy feedback from supernovae can be much less likely to influence the SSC formation. Although the “implosive formation scenario” described here can provide a clue to the origin of GCs in general, we have not yet reproduced the observed Fundamental Plane of GCs (in M31 and the Galaxy) and mass-size relation of GCs. Therefore, it is our future studies to check whether the implosive scenario can explain self-consistently the observed scaling relations of GCs and chemical properties of GCs.
