Abstract

We reconsider the conflict between recent calculations of the semileptonic branching ratio of the $B$ meson and the experimentally measured rate. Such calculations depend crucially on the application of “local duality” in nonleptonic decays, and we discuss the relation of this assumption to the weaker assumptions required to compute the semileptonic decay rate. We suggest that the discrepancy between theory and experiment might be due to the channel with two charm quarks in the final state, either because of a small value for $m_c$ or because of a failure of local duality. We examine the experimental consequences of such solutions for the charm multiplicity in $B$ decays.
I. INTRODUCTION

Because of the large energy which is released, the decay of a heavy quark is essentially a short distance process. This simple observation has led to much recent progress in the calculation of the inclusive decays of hadrons containing a heavy quark [1–7]. The method relies on the construction of a systematic expansion in the inverse of the energy release, given approximately by the heavy quark mass, and hence works most reliably in the bottom system. In fact, it is expected that certain features of inclusive bottom hadron decays may be reliably predicted with the accuracy of a few percent.

Considerable attention has been paid to inclusive semileptonic [2–5] and rare [6,7] \( B \) decays, both to total rates and to lepton and photon energy spectra. There is little controversy that these calculations rest on a firm theoretical foundation. However, it has been suggested to extend these methods to include nonleptonic decays as well [6,8]. This proposal has led to an intriguing conflict with experiment, as the predicted nonleptonic widths differ significantly from those which may be extracted from the measured semileptonic branching ratio of the \( B \) meson [9]. In this calculation, the short-distance expansion has been carried out to third order in the inverse mass \( 1/m_b \), and a reasonable analysis leads the authors of Ref. [9] to the conclusion that it would be unnatural to find the source of the discrepancy in uncalculated terms of higher dimension or higher order in \( \alpha_s \).

It is the purpose of this article to reconsider this problem, in particular the assumptions on which the computation is based. In Section II, we review the techniques used to treat inclusive decay rates, with an eye to emphasizing the differences between the theoretical foundations underlying the calculations of semileptonic and nonleptonic decays. In Section III, we discuss the possible discrepancy between theory and experiment in the \( B \) semileptonic branching ratio. This might be resolved by an unusually small value for \( m_c \), or might involve the failure of the key assumption, “local duality”, underlying the calculation of the nonleptonic rate. In either case the enhancement of decays into final states with two charm quarks is a likely consequence. In Section IV we examine the implications of this for
the charm multiplicity in $B$ decays, for which present data do not seem to support an enhancement resulting from the $b \to c\bar{c}s$ process. The unusual feature of the data on inclusive $B$ decays is neither the semileptonic branching ratio alone, nor the charm multiplicity alone, but rather the combination of the two. Brief concluding remarks are given in Section V.

**II. THEORETICAL TECHNIQUES**

The weak decay of $b$ quarks is mediated by operators of the form

$$\mathcal{O} = J^\mu_k J_{\ell\mu},$$  \hspace{1cm} (2.1)

where

$$J^\mu_k = \bar{q}\gamma^\mu (1 - \gamma^5) b,$$

$$J^\mu_\ell = \bar{q}_\ell \gamma^\mu (1 - \gamma^5) q_2 \quad \text{or} \quad \bar{\ell}\gamma^\mu (1 - \gamma^5) \nu_\ell$$  \hspace{1cm} (2.2)

are fermion bilinears. The inclusive decay rate is given by a sum over all possible final states $X$ with the correct quantum numbers,

$$\Gamma \sim \sum_X \langle B | \mathcal{O}^\dagger | X \rangle \langle X | \mathcal{O} | B \rangle.$$  \hspace{1cm} (2.3)

In this article we adopt the notation that a generic $B$ meson contains a $b$ quark, rather than a $\bar{b}$ quark. The optical theorem may be used to rewrite Eq. (2.3) as the imaginary part of a forward scattering amplitude,

$$\Gamma \sim \text{Im} \langle B | T \{ \mathcal{O}^\dagger, \mathcal{O} \} | B \rangle.$$  \hspace{1cm} (2.4)

One then would like to use perturbative QCD to extract information about the time-ordered product appearing in Eq. (2.4). The extent to which this is possible is precisely the extent to which inclusive decay rates may be calculated reliably.

In the case of semileptonic decays, one may follow a systematic procedure to justify the application of perturbative QCD [1]. Up to negligible corrections of order $\alpha_{EM}$ and $G_F$, one may factorize the matrix element of the four-fermion operator,
\[ \langle X \ell(p_\ell)\bar{\nu}(p_\nu) \mid J_{\ell\mu}^\mu J_{\ell\mu} \mid B \rangle = \langle X \mid J_{\ell\mu}^\mu \mid B \rangle \langle \ell(p_\ell)\bar{\nu}(p_\nu) \mid J_{\ell\mu} \mid 0 \rangle , \]  

(2.5)

and consider only the time-ordered product of the quark currents. One then finds an expression in which the integral over the momenta of the leptons is explicit,

\[ \Gamma \sim \int dy \, dv \cdot \hat{q} \, dq^2 \, L_{\mu\nu}(v \cdot \hat{q}, \hat{q}^2, y) \, W_{\mu\nu}(v \cdot \hat{q}, \hat{q}^2) , \]  

(2.6)

where \( L_{\mu\nu} \) is the lepton tensor and \( W_{\mu\nu} \) the hadron tensor. Here the momentum of the external \( b \) quark is written as \( p_b^\mu = m_b v^\mu \). The other independent kinematic variables are \( q^\mu = p_\ell^\mu + p_\nu^\mu \) and \( y = 2E_\ell/m_b \). It is convenient to scale all momenta by \( m_b \), so \( \hat{q} = q/m_b \). The hadronic tensor is given by

\[
W_{\mu\nu} = \sum_X \langle B \mid J_{\ell\mu}^\mu \mid X \rangle \langle X \mid J_{\ell\mu}^\mu \mid B \rangle \\
= -2\text{Im} \langle B \mid i \int dx \, e^{i\hat{q} \cdot x} T \{ J_{\ell\mu}(x), J_{\ell\mu}(0) \} \mid B \rangle \\
\equiv -2\text{Im} T_{\mu\nu} .
\]  

(2.7)

One may perform the integrals in \( y, v \cdot \hat{q} \) and \( \hat{q}^2 \) in Eq. (2.6) to compute the total semileptonic decay rate, or leave some of them unintegrated to obtain various differential distributions.

The doubly differential distribution \( d\Gamma/dy \, dq^2 \) is a useful case to consider. Here we must perform the integral over \( v \cdot \hat{q} \), for \( y \) and \( \hat{q}^2 \) fixed. The range of integration for \( v \cdot \hat{q} \) is given by \((y + \hat{q}^2/y)/2 \leq v \cdot \hat{q} \leq (1 + \hat{q}^2 - \hat{m}_q^2)/2\), where \( m_q \) is the mass of the quark to which the \( b \) decays, and \( \hat{m}_q = m_q/m_b \). This integration is pictured in Fig. 1a, along with the analytic structure of \( T_{\mu\nu} \) in the \( v \cdot \hat{q} \) plane \([1, 10]\). The absence of a cut along the real axis in the region \((1 + \hat{q}^2 - \hat{m}_q^2)/2 < v \cdot \hat{q} < ((2 + \hat{m}_q)^2 - \hat{q}^2 - 1)/2\) is simple to understand in terms of the invariant mass \( p_H \) of the intermediate hadronic state. Such a state may contain no \( b \) quarks, in which case it is subject to the restriction \( p_H^2 = (m_b v - q)^2 \geq m_q^2 \) (the left-hand cut), or it may contain \( b\bar{b}q \), in which case \( p_H^2 = (m_b v + q)^2 \geq (2m_b + m_q)^2 \) (the right-hand cut). Except in the limit \( \hat{q}^2 = \hat{q}_{\text{max}}^2 = (1 - \hat{m}_q)^2 \) and \( m_q \to 0 \), the two cuts do not pinch.

\* The discussion of the analytic structure of \( T_{\mu\nu} \) given in Ref. [3] is erroneous. We thank B. Grinstein and A.I. Vainshtein for discussions of this point.
In Fig. 1a, we have already included only the imaginary part of $T^{\mu\nu}$ by integrating over the top of the cut and then back underneath it. In general, $T^{\mu\nu}$ along the physical cut will depend on $v \cdot q$ in a complicated nonperturbative way. We do not necessarily know how to compute in QCD in the physical region where there are threshold effects. However, we may use Cauchy’s Theorem to deform the contour of integration until it lies away from the cut everywhere except at its endpoints, as illustrated in Fig. 1b. Along the new contour, we are far from the physical region, and we may perform an operator product expansion for $T^{\mu\nu}$ in perturbative QCD. Only far from any physical intermediate states is such a calculation necessarily valid. However, this is enough to allow us to compute reliably certain smooth integrals of $T^{\mu\nu}$ by deforming the contour of integration into the unphysical region. That we can compute integrals of $T^{\mu\nu}$ in perturbation theory in this way is the property of “global duality”.

Unfortunately, the contour in Fig. 1 must still approach the physical cut near the endpoints of the integration. This introduces an uncertainty into the calculation which cannot be avoided. Still, one has two arguments that this uncertainty is likely to be small. First, for large $m_b$, the portion of the contour which is within $\Lambda_{\text{QCD}}$ of the physical cut scales as $\Lambda_{\text{QCD}}/m_b$ and thus makes a small contribution to the total integral. Second, if the energy release into the intermediate hadronic system is large compared to $\Lambda_{\text{QCD}}$, it is reasonable to expect that $T^{\mu\nu}$ will be well approximated by perturbative QCD even in the physical region. This is because in this region the cut is dominated by multiparticle states, and hence the strength of the imaginary part of $T^{\mu\nu}$ is a relatively smooth function of the energy. While new thresholds associated with the production of additional pions are found along the cut even in this region, their effect is small compared to the smooth background of states to which they are being added.

This intuition, that for large enough energies one may perform the operator product expansion directly in the physical region, is “local duality”. While it is a reasonable property for QCD to have, it is obviously a stronger assumption than that of global duality. In particular, it cannot be justified by analytic continuation into the complex plane. Rather, it
rests on one’s sense of how QCD ought to behave at high energies. It is clear, as well, that the
energy at which local duality takes effect will depend on the operators which appear in the
time-ordered product. Hence the fact that local duality appears to work at a given energy
in one process, such as in electron-positron annihilation into hadrons, may be suggestive but
does not prove that it should hold at the same energy in another process.

To compute the inclusive semileptonic decay rate, then, one may use global duality except
in a region along the contour of order \( \Lambda_{\text{QCD}}/m_q \), where one must approach the physical cut.
In this small region one must resort to local duality to justify the operator product expansion.

Let us now turn to inclusive nonleptonic decays. Here there is no analogue of the factor-
ization (2.5) which we had in the semileptonic case. Hence there is no “external” momentum
\( q \) in which one may deform the contour away from the physical region, leaving one unable
to use global duality in the transition to perturbative QCD. In this case, one is forced to
invoke local duality from the outset if one is to argue that the the time-ordered product \( T^{\mu \nu} \)
is computable. This clearly puts the calculation of inclusive nonleptonic \( B \) decays on a less
secure theoretical foundation than that of inclusive semileptonic \( B \) decays.

Nonetheless, we do not mean to assert that the assumption of local duality in nonleptonic
decays is inherently unreasonable, merely that it is the least reliable aspect of the computa-
tion. In fact, it is not entirely clear what it is reasonable to expect in this case. On the one
hand, the energy released when a \( b \) quark decays is certainly large compared to \( \Lambda_{\text{QCD}} \). On
the other, the decay is initially into three strongly interacting particles (rather than into only
one for semileptonic decays), and the energy per strongly interacting particle is not really
so large. (Note that in the semileptonic case, the point at which the contour approaches the
cut and local duality must be invoked is conveniently the point of maximum recoil of the
final state quark, where local duality is expected to work best.) What we propose is that the
comparison of the nonleptonic decay rate, as computed via the operator product expansion,
with experiment be taken as a direct test of local duality in this process. As such, it is a
probe of a property of QCD in an interesting kinematic region, and nonleptonic \( B \) decay
well deserves the intense scrutiny which it has recently been accorded.
III. THE SEMILEPTONIC BRANCHING FRACTION OF B MESONS

The experimental implications of inclusive nonleptonic decays of \( B \) mesons have recently been discussed in great detail by Bigi, Blok, Shifman and Vainshtein [9]. Since the semileptonic branching ratio of the \( B \) is relatively well-measured, they use their calculation of the nonleptonic decay rate to predict this quantity. Their conclusion is that the semileptonic branching ratio which comes out of their computation is unacceptably high, corresponding to a nonleptonic width which is too low by at least 15-20\%. In this section we will reconsider their analysis.

The inclusive decay rate of the \( B \) meson may be divided into parts based on the flavor quantum numbers of the final state,

\[
\Gamma_{\text{TOT}} = \Gamma(b \to c \ell \bar{\nu}) + \Gamma(b \to c \bar{u} \ell) + \Gamma(b \to c \bar{s} \ell).
\]  

(3.1)

Here we neglect rare processes, such as those mediated by an underlying \( b \to u \) transition or penguin-induced decays. By \( d' \) and \( s' \) we mean the approximate flavor eigenstates (\( d' = d \cos \theta_1 - s \sin \theta_1, \ s' = d \sin \theta_1 + s \cos \theta_1 \)) which couple to \( u \) and \( c \), respectively, and we ignore the effect of the strange quark mass. It is convenient to normalize the inclusive partial rates to the semielectronic rate, defining

\[
R_{ud} = \frac{\Gamma(b \to c \bar{u} \ell)}{3\Gamma(b \to c e \bar{\nu})}, \quad R_{cs} = \frac{\Gamma(b \to c \bar{s} \ell)}{3\Gamma(b \to c e \bar{\nu})}.
\]  

(3.2)

The full semileptonic width may be written in terms of the semielectronic width as

\[
\Gamma(b \to c \ell \bar{\nu}) = 3f(m_\tau)\Gamma(b \to c e \bar{\nu}),
\]  

(3.3)

where the factor \( 3f(m_\tau) \) accounts for the three flavors of lepton, with a phase space suppression which takes into account the \( \tau \) mass. Then, since the semileptonic branching ratio is given by \( Br(b \to c \ell \bar{\nu}) = \Gamma(b \to c \ell \bar{\nu})/\Gamma_{\text{TOT}} \), we may rewrite Eq. (3.1) in the form

\[
R_{ud} + R_{cs} = f(m_\tau) 1 - \frac{Br(b \to c \ell \bar{\nu})}{Br(b \to c e \bar{\nu})}.
\]  

(3.4)

The measured partial semileptonic branching fractions are [11,12]
leading to a total semileptonic branching fraction $Br(b \to c \ell \bar{v})$ of $23.8 \pm 0.9\%$, with the experimental errors added in quadrature. Of the semileptonic rate, 11% comes from decays to $\tau$, corresponding to a phase space suppression factor $f(\hat{m}_\tau) = 0.74$, consistent with what one would expect in free quark decay [5,13]. If we substitute the measured branching fractions into the right-hand side of Eq. (3.4), we find

$$R_{ud} + R_{cs} = 2.37 \pm 0.12.$$  \tag{3.6}$$

We now compare this constraint with the theoretical calculations of $R_{ud}$ and $R_{cs}$.

The ratios $R_{ud}$ and $R_{cs}$ depend on the total rates $\Gamma(b \to c e \bar{v})$, $\Gamma(b \to c u \bar{d})$ and $\Gamma(b \to c \bar{c}s')$. Each of these has a theoretical expansion in terms of $\alpha_s(\mu)$ and $1/m_b$. Since corrections of order $1/m_b$ vanish and those of order $1/m_b^2$ are numerically expected to be at the few percent level [1-4,6,7,9], we include here only the radiative corrections. Neglecting terms of order $\alpha_s^2(\mu)$, the expansions take the form

$$\Gamma(b \to c e \bar{v}) = \Gamma_0 I(\hat{m}_c, 0) \cdot \left\{ 1 - \frac{2\alpha_s(\mu)}{3\pi} \left( \pi^2 - \frac{25}{4} + \delta_{u1}(\hat{m}_c) \right) \right\},$$

$$\Gamma(b \to c u \bar{d}) = \Gamma_0 I(\hat{m}_c, 0) \cdot 3\eta(\mu) \left\{ 1 - \frac{2\alpha_s(\mu)}{3\pi} \left( \pi^2 - \frac{31}{4} + \delta_{ud}(\hat{m}_c) \right) + J_2(\mu) \right\},$$

$$\Gamma(b \to c \bar{c}s') = \Gamma_0 I(\hat{m}_c, 0) \cdot 3\eta(\mu) G(\hat{m}_c) \left\{ 1 - \frac{2\alpha_s(\mu)}{3\pi} \left( \pi^2 - \frac{31}{4} + \delta_{cs}(\hat{m}_c) \right) + J_2(\mu) \right\}.  \tag{3.7}$$

The prefactor $\Gamma_0 = G_F^2 m_b^5 |V_{cb}|^2 / 192\pi^3$ will cancel in the ratios $R_{ud}$ and $R_{cs}$, as will the charm quark phase space suppression $I(\hat{m}_c, 0)$ [13], to be discussed below.

The radiative corrections have been computed analytically to order $\alpha_s$ in the limit $m_c = 0$, and for semileptonic decays up to one numerical integration for general $m_c$ [14]. For semileptonic decays we absorb the correction due to $\hat{m}_c \neq 0$ into $\delta_{u1}(\hat{m}_c)$ and present the numerical value of $\delta_{u1}(\hat{m}_c)$ below. Finite charm mass effects for nonleptonic decays are absorbed into $\delta_{ud}(\hat{m}_c)$ and $\delta_{cs}(\hat{m}_c)$. Because these quantities have not been computed, we
present numerical results in the case of nonleptonic decays only for $\hat{m}_c = 0$. The expressions for $\Gamma(b \to c\bar{u}d')$ and $\Gamma(b \to c\bar{e}s')$ in Eq. (3.7) are somewhat more complicated than that for $\Gamma(b \to c\bar{e}\bar{\nu})$, due to renormalization group running between $\mu = M_W$ and $\mu = m_b$. The leading logarithms are resummed into $\eta = (2L_+^2 + L_+^2)/3$, where [15]

$$L_+ = \left[ \frac{\alpha_s(\mu)}{\alpha_s(M_W)} \right]^{-6/23}, \quad L_- = \left[ \frac{\alpha_s(\mu)}{\alpha_s(M_W)} \right]^{12/23}. \quad (3.8)$$

The subleading logarithms, which must be included if terms of order $\alpha_s(\mu)$ are also to be kept, are assembled into $J_2$,

$$J_2 = \frac{2\alpha_s(\mu)}{3\pi} \left( \frac{19}{4} + 6 \log \frac{\mu}{m_b} \right) \frac{L_+^2 - L_+^2}{2L_+^2 + L_+^2} + 2 \left( \frac{\alpha_s(\mu) - \alpha_s(M_W)}{\pi} \right) \frac{2L_+^2 \rho_+ + L_-^2 \rho_-}{2L_+^2 + L_-^2}, \quad (3.9)$$

where $\rho_+ = -\frac{6473}{1250} = -0.51$ and $\rho_- = \frac{9371}{6348} = 1.47$ arise from two-loop anomalous dimensions [16]. The factor 3 in Eq. (3.7) is for the sum over colors in the final state. Finally, there is an additional phase space suppression $G(\hat{m}_c)$ in $\Gamma(b \to c\bar{e}s')$ because of the masses of the two charm quarks. This factor is given by [13]

$$G(\hat{m}_c) = \frac{I(\hat{m}_c, \hat{m}_c)}{I(\hat{m}_c, 0)}, \quad (3.10)$$

where

$$I(x, 0) = (1 - x^4)(1 - 8x^2 + x^4) - 24x^4 \log x,$$

$$I(x, x) = \sqrt{1 - 4x^2}(1 - 14x^2 - 2x^4 - 12x^6) + 24x^4(1 - x^4) \log \left( \frac{1 + \sqrt{1 - 4x^2}}{1 - \sqrt{1 - 4x^2}} \right). \quad (3.11)$$

In terms of the theoretical expressions (3.7) for the partial widths, the ratios take the form

$$R_{ud} = P(\mu) + \delta P_{ud}(\mu, \hat{m}_c),$$

$$R_{cs} = G(\hat{m}_c) \left[ P(\mu) + \delta P_{cs}(\mu, \hat{m}_c) \right], \quad (3.12)$$

where

$$P(\mu) = \eta(\mu) \left[ 1 + \frac{\alpha_s(\mu)}{\pi} + J_2(\mu) \right],$$

$$\delta P_{ud}(\mu, \hat{m}_c) = \eta(\mu) \frac{2\alpha_s(\mu)}{3\pi} \left[ \delta_{ud}(\hat{m}_c) - \delta_{ud}(\hat{m}_c) \right],$$
\[ \delta P_{cs}(\mu, \hat{m}_c) = \eta(\mu) \frac{2\alpha_s(\mu)}{3\pi} \left[ \delta_{s,1}(\hat{m}_c) - \delta_{cs}(\hat{m}_c) \right] \]

parametrize the radiative corrections. As emphasized in Ref. [9], if the theoretical expressions (3.12) are inserted, then Eq. (3.6) is not well satisfied. For example, if one simply takes the reasonable values \( \mu = m_b = 4.8 \text{ GeV} \), \( m_c = 1.5 \text{ GeV} \), \( \Lambda_{\overline{\text{MS}}}^{[5]} = 180 \text{ MeV} \) and \( \delta P_{ud} = \delta P_{cs} = 0 \), then \( P(\mu) = 1.27 \), \( G(\hat{m}_c) = 0.36 \) and the left-hand side of Eq. (3.6) is only 1.73. We are thus tempted to push the uncertainties in the calculation as far as is reasonable, in order to see how much of the discrepancy can be resolved within the context of the operator product expansion.

The largest uncertainty in the theoretical expression for \( R_{ud} + R_{cs} \) comes from the choice of the charm and bottom masses. Up to certain ambiguities which have recently been discussed [17], within perturbation theory these masses should be taken to be the pole masses [3,18]. These masses have not been determined with much precision. However, within the heavy quark expansion, the difference between \( m_c \) and \( m_b \) is much more precisely known, in terms of the spin-averaged \( D \) meson and \( B \) meson masses:

\[ m_b - m_c = \langle M_B \rangle_{\text{ave.}} - \langle M_D \rangle_{\text{ave.}} = 3.34 \text{ GeV} . \]  

In what follows, we will hold \( m_b - m_c \) fixed, and consider variations of \( m_b \) only. A reasonably conservative range for \( m_b \) might be \( 4.4 \text{ GeV} \leq m_b \leq 5.0 \text{ GeV} \), which corresponds to \( 0.24 \leq \hat{m}_c \leq 0.33 \). In Fig. 2, we plot \( G(\hat{m}_c) \) as a function of \( m_b \), using the constraint (3.14). In Fig. 3, we plot \( P(\mu) \) for a variety of values of the QCD scale \( \Lambda_{\overline{\text{MS}}}^{[5]} \) [11].

We start by considering \( R_{ud} \), for which the calculation is likely to be more reliable, since it is less sensitive to \( \hat{m}_c \). There is uncertainty in the radiative correction \( P(\mu) \) from the choice of the renormalization scale \( \mu \). The usual choice \( \mu = m_b \) is motivated by the fact that the total energy released in the decay is \( m_b \). However, this energy has to be divided between three particles, so perhaps the appropriate scale is lower. For \( \mu = 1.6 \text{ GeV} \approx m_b/3 \), a reasonable lower limit, and \( \Lambda_{\overline{\text{MS}}}^{[5]} = 180 \text{ MeV} \), we find \( P(\mu) = 1.45 \), a modest enhancement over \( \mu = 4.8 \text{ GeV} \). If \( \Lambda_{\overline{\text{MS}}}^{[5]} \) is taken as high as 220 MeV, we have \( P(\mu) = 1.52 \), which
makes a small additional difference. The uncertainty in $\delta P_{ud}$ is harder to estimate, since $\delta_{ud}(\hat{m}_c)$ has not been calculated. However, one may extract $\delta_{n,1}(\hat{m}_c)$ by doing a numerical integration of the formulas in Ref. [14]. For $\hat{m}_c = 0.30$, we find $\delta_{n,1} = -1.11$, corresponding to $(2\alpha_s(m_b)/3\pi)\delta_{n,1}(\hat{m}_c) = -0.050$. The magnitude of this correction grows approximately linearly with $\hat{m}_c$, and for $\hat{m}_c = 0.33$, we have $\delta_{n,1} = -1.20$. Hence the term is small and actually reduces $R_{ud}$, although one might expect it to cancel in whole or in part against the term proportional to $\delta_{ud}(\hat{m}_c)$. What we can conclude at this point is that the error associated with ignoring the charm quark mass in the radiative corrections is likely to be no larger than $\pm 0.05$, and henceforth we will neglect this effect.

The leading nonperturbative strong interaction corrections to $R_{ud}$ and $R_{cs}$ are characterized by the two dimensionless quantities $K_b = -(B(v)|\bar{b}_b(iD)^2b_c|B(v))/2m_b^2$ and $G_b = \langle B(v)|\bar{b}_b g_s G_{\mu\nu} \sigma^{\mu\nu} b_c |B(v)\rangle/4m_b^2$. Because it breaks the heavy quark spin symmetry, the parameter $G_b$ may be determined from the measured $B^*-B$ mass splitting, but the value of $K_b$ is not known. Fortunately, $K_b$ does not occur in the nonperturbative correction to $R_{ud}$. (Using the “smearing” technique of Ref. [3], this cancelation arises because $\Gamma(b \to c\bar{u}d)$ and $\Gamma(b \to c\bar{e}\bar{\nu})$ have the same dependence on $m_b$.) For $R_{ud}$, then, we are more confident than for $R_{cs}$ that the nonperturbative QCD corrections are small. Note, however, that there is a contribution to the mass difference in Eq. (3.14) involving $K_b$ and $K_z$, which we have neglected.

The above estimates lead us to the conclusion that with the effects we have included in the operator product expansion, it is difficult to avoid the upper bound $R_{ud} \leq 1.52$. If this is true, then Eq. (3.6) would imply $R_{cs} \geq 0.85$. This can barely be achieved in the theoretical expressions we have given. If we vary $4.4 \text{ GeV} \leq m_b \leq 5.0 \text{ GeV}$, as suggested above, then $0.27 \leq G(\hat{m}_c) \leq 0.58$. Estimating the radiative corrections as before, with $\Lambda_{\overline{MS}}^{[5]} = 220 \text{ MeV}$, this suggests the upper limit $R_{cs} \leq 0.89$, or $R_{ud} + R_{cs} \leq 2.43$. This is in agreement with experiment, but on the other hand, it requires us to push all the freedom in the calculation in the same direction, perhaps further than is reasonable. If one were to take the point of view that $\mu = 2.4 \text{ GeV} \approx m_b/2$ were the lowest reasonable value for $\mu$, then one would have
the constraints $R_{ud} \leq 1.44$, $R_{cs} \leq 0.83$ and $R_{ud} + R_{cs} \leq 2.27$. If one were further to require $m_b \geq 4.6\text{ GeV}$, one would have $R_{cs} \leq 0.67$ and $R_{ud} + R_{cs} \leq 2.10$. In this case, one might consider the discrepancy with experiment to be a more serious issue.

Another possibility is that the relevant scale for the radiative corrections in the decay to two charm quarks is considerably lower than that for the final state with a single charm. Since the rest masses of the two charm quarks absorb approximately 60% of the energy available in the decay, the strongly interacting particles are not emitted with very large momenta. For example, the average energy of the strange quark in the decay $b \to c \bar{c} s$, computed at tree level, is only about 1 GeV. With such a low energy the procedure of estimating the value of higher order QCD corrections by varying the subtraction point $\mu$ is of dubious value. In fact one might question whether any finite order of perturbation theory is adequate and whether threshold effects that cause a violation of local duality are important.

It is evident from this discussion that nothing is particularly clear. Although the data on inclusive nonleptonic decays can almost be accounted for by squeezing the input parameters, one might feel a little nervous about the necessity of such a conspiracy. After all, as mentioned earlier the “reasonable” values $\mu = m_b = 4.8\text{ GeV}$, $m_c = 1.5\text{ GeV}$ and $A_{	ext{MS}}^{(5)} = 180\text{ MeV}$ lead to $R_{ud} = 1.27$ and $R_{cs} = 0.46$, far short of the mark. An enhancement of approximately 40% in the nonleptonic rate is called for. If one were to require this effect to be found entirely in $R_{cs}$, it would amount to more than a factor of two. While we are less inclined than the authors of Ref. [9] to insist that something is amiss, it is nonetheless intriguing to consider the possibility that the data indicate an enhancement of the nonleptonic rate over and above what we have included in the operator product expansion. Where might such an enhancement come from?

The simplest explanation would be that due to a failure of local duality, the inclusive nonleptonic decay rate is simply not calculable to better than 40% or so. This is certainly a discouraging explanation, in that if it were true then there would be very little one could say in detail about why local duality, and hence the calculation, had failed. One was simply
unlucky. On the other hand, this explanation may well be correct. While we expect local
duality to hold in the asymptotic limit of infinite b quark mass, we have little to guide us
in estimating how heavy the b quark actually needs to be in practical terms. In particular,
it is not relevant to consider, at low orders in QCD perturbation theory, the size of a
few subleading terms which appear in the operator product expansion itself. The matrix
elements which appear in this expansion are sensitive to details of the B meson bound state,
but they are explicitly not sensitive to resonance effects in the final hadronic state.

If local duality fails, it could well fail differently in the \( \Gamma(b \to c\bar{u}d') \) and \( \Gamma(b \to c\bar{c}s') \)
channels. In fact, we would expect it to fail worse in the channel with two charm quarks,
since we expect the final states to be characterized by lower particle multiplicity and be
closer to the resonance-dominated regime. Local duality, by contrast, is applicable only
in the regime where the effect of individual resonance thresholds is small compared to the
almost smooth “continuum” of multiparticle states. On the other hand, the phase space
suppression from the two final state charm quarks means that unless \( m_c \) is unusually small,
only thirty percent or so of the inclusive nonleptonic rate comes from the \( \Gamma(b \to c\bar{c}s') \)
channel. Hence, to account for an enhancement of the full nonleptonic rate by forty percent
purely from \( b \to c\bar{c}s' \) would require a dramatic failure of local duality in this channel.

**IV. Experimental Consequences of an Enhancement of \( R_{cs} \)**

Either through a failure of local duality, or from an unusually small value for \( m_c \), or
because of a combination of these effects, the value of \( R_{cs} \) is likely to be near unity in order
to account for the measured \( B \) semileptonic branching ratio. This corresponds to about
one-third of \( B \) decays arising from the \( b \to c\bar{c}s' \) process. One consequence of this is a large
number of charmed quarks per \( B \) decay,

\[
n_c = 1 + R_{cs} \frac{Br(B \to X_c \ell\bar{\nu})}{f(\bar{m}_\tau)}.
\]

(4.1)

We remind the reader that we have adopted the notation that a generic \( B \) meson contains
a \( b \) quark, rather than a \( \bar{b} \) quark. Using \( Br(B \to X_c \ell\bar{\nu}) = 23.8\% \) and \( f(\bar{m}_\tau) = 0.74 \) in
Eq. (4.1) yields
\[ n_c = 1.00 + 0.32 R_{cs}, \]  
(4.2)
which for the values of \( R_{cs} \) necessary to explain the semileptonic branching ratio would indicate \( n_c \approx 1.3 \).

There are contributions to the experimental value of \( n_c \) from charmed mesons, charmed baryons, and \( c \bar{c} \) resonances. The number of charged and neutral \( D \) mesons per decay, summed over \( B \) and \( \bar{B} \), has been measured to be [19]
\[ n_{D\pm} = 0.246 \pm 0.031 \pm 0.025, \]
\[ n_{D^0, \bar{D}^0} = 0.567 \pm 0.040 \pm 0.023. \]  
(4.3)
The branching ratio to \( D_s^\pm \) mesons has not yet been determined, because no absolute \( D_s \) branching ratio has been measured. However, it is known that [20]
\[ n_{D_s^\pm} = (0.1221 \pm 0.0051 \pm 0.0089) \left[ \frac{3.7\%}{Br(D_s \to \phi \pi)} \right], \]  
(4.4)
and the branching ratio for \( D_s \to \phi \pi \) is expected to be about 3.7%.

We must include in \( n_c \) twice the inclusive branching ratio to all \( c\bar{c} \) resonances which are below \( D\bar{D} \) threshold. The measured inclusive branching ratio to \( \psi \) is \((1.11 \pm 0.08)\%\), including feed-down from \( \psi' \) and \( \chi_c \) decays [19]. It is also known that \( Br(B \to \psi' X) = (0.32 \pm 0.05)\% \), \( Br(B \to \chi_c X) = (0.66 \pm 0.20)\% \) and \( Br(B \to \eta_c X) < 1\% \). Hence we expect that the inclusive \( B \) branching ratio to charmonium states below \( D\bar{D} \) threshold is about 2%.

The inclusive \( B \) decay rate to baryons is about 6% [19]. While it is commonly believed that these baryons arise predominantly from the \( b \to c\bar{u}d' \) process, giving \( \Lambda_c X \) final states, we argue elsewhere [21] that a large fraction of \( B \) decays to baryons actually arise from the \( b \to c\bar{c}s' \) process, which gives final states with both a charm baryon and an anticharm baryon, such as \( \Xi_c \bar{\Lambda}_c X \). Evidence for this interpretation comes from the experimental distribution of \( \Lambda_c \) momenta, which shows that the \( \Lambda_c \)’s produced in \( B \) or \( \bar{B} \) decay are recoiling against a state
with a mass greater than or equal to the mass of the $\Xi_c$ [22-24]. This novel interpretation of $B$ decays to baryons can be consistent with the measured $\Lambda\ell^\pm$ correlations if $Br(\Xi_c \to \Lambda X)/Br(\Lambda_c \to \Lambda X)$ is large [21].

Even if $B$ decay to baryons predominantly gives final states with both a charm and an anticharm baryon, the data summarized above do not provide supporting evidence for a value of $n_c$ around 1.3. Given the uncertainties, however, such a large value for the number of charmed hadrons per $B$ decay is perhaps not excluded. From our perspective the curious feature of the data on inclusive $B$ decay is not the measured semileptonic branching ratio alone, but rather the combination of it with the data on charm multiplicity in these decays.

In this paper we have neglected $B$ decays that do not arise from an underlying $b \to c$ transition. Other possible processes include the $b \to u$ transition and contributions from penguin-type diagrams. While it is very unlikely that such sources contribute significantly to the nonleptonic decay rate, this assumption can be tested experimentally, if enough branching ratios can be measured. The fraction of $B$ decays arising from the $b \to c$ transition is given by the sum of the $B$ branching ratio to charmonium states below $D\bar{D}$ threshold, the branching ratio to states containing at least one charmed baryon, and the branching ratios to the ground state charmed mesons, $Br(B \to D^0 X)$, $Br(B \to D^+ X)$ and $Br(B \to D_s^+ X)$. Note that the inclusive charm yields reported in Eqs. (4.3) and (4.4) are actually sums of branching ratios (for example, neglecting $CP$ violation, $n_{D\pm} = Br(B \to D^+ X) + Br(B \to D^- X)$). However, it should be possible with enough data to extract the individual branching ratios themselves.

For example, one could count the number of $DD$ (or $\overline{D}D$) events per $B\overline{B}$ event at the $\Upsilon(4S)$,

$$n(DD) = (1 - b) \ Br(B \to DX) \ Br(\overline{B} \to DX)$$
$$+ \frac{b}{2} \left[ Br(B \to DX) \ Br(B \to DX) + Br(\overline{B} \to DX) \ Br(\overline{B} \to DX) \right]$$
$$\approx (1 - b) Br(B \to DX) Br(\overline{B} \to DX) + \frac{b}{2} Br(B \to DX) Br(B \to DX) , \quad (4.5)$$

and
\begin{equation}
\begin{split}
n(DD_s^\pm) &= (1 - b) \left[ Br(B \to DX) Br(\overline{B} \to D_s^\pm X) + Br(B \to D_s^\pm X) Br(\overline{B} \to DX) \right] \\
& \quad + \frac{b}{2} \left[ Br(B \to DX) Br(B \to D_s^\pm X) + Br(\overline{B} \to DX) Br(\overline{B} \to D_s^\pm X) \right] \\
& \approx (1 - b) Br(B \to DX) Br(\overline{B} \to D_s^\pm X),
\end{split}
\end{equation}

where \( b \approx 0.076 \) is the \( B - \overline{B} \) mixing parameter \cite{25}. Combining Eqs. (4.3) and (4.5), we may extract \( Br(B \to DX) \) and \( Br(\overline{B} \to \overline{DX}) \) separately, if we neglect \( CP \) violation and impose the constraint \( Br(\overline{B} \to DX) = Br(B \to \overline{DX}) \). Analogously, we may extract \( Br(B \to D_s^\pm X) \) and \( Br(B \to D_s^\pm X) \). Another method for determining individual branching ratios would involve tagging the flavor of the \( B \) which produced the charmed hadron by measuring the charge of a hard primary lepton from the other \( B \) in the event.

Invoking a large violation of local duality has some implications for the pattern of \( B \) meson decays which may be different from what would be expected if local duality held and an unusually small value of \( m_c \) were used to explain the measured \( B \) semileptonic branching ratio. For example, a violation of local duality in the \( b \to c\bar{c}s \) channel could lead to quite different lifetimes for the \( B, B_s \) and \( \Lambda_b \), differences which are small in the operator product expansion because they arise only from higher dimension operators. However, since the effective Hamiltonian for this process has isospin zero, the equality of the \( \overline{B}^0 \) and \( B^- \) lifetimes would not be disturbed. Similarly, violations of local duality in \( b \to c\bar{u}d' \) could lead to unequal \( \overline{B}^0 \) and \( B^- \) lifetimes. \( B \) decay event shapes can also provide a test of the free quark decay picture for the \( b \to c\bar{u}d' \) decay channel \cite{26}.

\section{V. CONCLUDING REMARKS}

We have examined whether the measured \( B \) meson semileptonic branching ratio can be explained within the conventional application of the operator product expansion, in which operators of low dimension are kept and perturbative corrections are included to a few orders in \( \alpha_s \). We have found that this scenario would require an unusually small value for \( m_c \). If instead the explanation lies outside the conventional application of the operator product expansion, then a failure of local duality in the \( b \to c\bar{c}s' \) channel is the likely explanation.
for the discrepancy with experiment. In either case, we expect the number of charmed hadrons per \( B \) decay to be approximately 1.3. Unfortunately, the present data on charm multiplicities do not support such a large value of \( n_\ast \). From our perspective, the unusual feature of inclusive \( B \) decay is not the semileptonic branching ratio alone, nor the charm multiplicity alone, but rather the combination of the two. Together, they would seem to suggest a significant violation of local duality in the \( b \to c\bar{u}d' \) nonleptonic decay process. From a theoretical point of view, however, such a resolution would be somewhat unsettling, as it would indicate a breakdown in the computation of the nonleptonic decay rate in the region where it is expected to be the most reliable; we understand why such a conclusion was resisted by the authors of Ref. [9]. Still, it remains an open possibility, indicating perhaps that the invocation of local duality in quark decay requires a considerably larger energy release than has been naively hoped or expected. Given the apparent difficulties in performing a reliable computation of the nonleptonic decay rate, then, the CKM matrix element \( V_{cb} \) should be extracted from the \( B \) semileptonic decay width rather than from the \( B \) lifetime. The uncertainties in such an extraction arise primarily from the choice of \( m_t \) and subtraction point \( \mu \), and are discussed in detail in Refs. [27,28].
