(Received 19 November 2004; published 9 May 2005)

We construct a consistent model of gravity where the tensor graviton mode is massive, while linearized equations for scalar and vector metric perturbations are not modified. The Friedmann equation acquires an extra dark-energy component leading to accelerated expansion. The mass of the graviton can be as large as \( \sim (10^{15} \text{ cm})^{-1} \), being constrained by the pulsar timing measurements. We argue that nonrelativistic gravitational waves can comprise the cold dark matter and may be detected by the future gravitational wave searches.

Introduction.—The current cosmological model is in beautiful agreement with the data [1]. However, it requires the introduction of exotic density components (dark matter, dark energy) with abundances highly tuned to baryonic matter. This motivates interest in modified theories of gravity deviating from the Einstein theory at large distance scales. Generically, in such theories the graviton has a nonzero mass. The common lore is that inverse graviton masses significantly smaller than the current Hubble scale are not phenomenologically allowed. In this Letter, we demonstrate that the inverse graviton mass can be not only significantly smaller than the current size of the Universe, but also many orders of magnitude smaller than the galactic scales. We argue that a massive graviton provides specific signatures for gravitational wave experiments and may even account for the cold dark matter (CDM) in the universe.

Recent studies of the Fierz–Pauli theory of massive gravity [2] and brane world scenarios where the four-dimensional graviton has a nonzero mass [3,4] strongly suggest [5–11] that Lorentz-invariant models of massive gravity suffer either from the presence of ghosts (fields with a wrong sign of the kinetic term) or from the van Dam–Veltman–Zakharov (vDVZ) discontinuity due to extra graviton polarizations [12,13] and strong coupling at the low energy scale. It is possible that the account for the effects of local curvature may solve these problems in some models [14–17]. Another possibility that has attracted attention very recently [18–22] is to allow for a violation of Lorentz invariance. In particular, a class of models was found [22] where the tensor graviton mode is massive, and vDVZ discontinuity and strong coupling problems are absent, while the absence of ghosts and rapid classical instabilities is ensured by the residual reparametrization symmetry

\[ x^i \rightarrow x^i + \xi^i(t), \]

(1)

\( \xi^i \) being the spatial coordinates. These models are the focus of the current Letter.

The model.—In the covariant formalism of Ref. [22] (see also Refs. [5,19]), the action for the theory of massive gravity contains the metric \( g_{\mu\nu} \) and four scalar Goldstone fields \( \phi^0 \) and \( \phi^i (i = 1, \ldots, 3) \). In the presence of the residual symmetry (1), it reads

\[ S = \int d^4x \sqrt{-g} \left[ -M_{Pl}^2 R + \Lambda^4 F(X, W^{ij}, \ldots) \right], \]

(2)

where \( X = m^2 \) and \( W^{ij} \) are the scalar quantities constructed from the Goldstone fields and the metric tensor,

\[ W^{ij} = g^{\mu\nu} \partial_\mu \phi^i \partial_\nu \phi^j - \frac{g^{\mu\nu} \partial_\mu \phi^0 \partial_\nu \phi^i g^{\lambda\rho} \partial_\lambda \phi^0 \partial_\rho \phi^j}{X}, \]

(3)

and \( F \) is a function to be constrained later. We assume that the Goldstone sector is characterized by a single energy scale \( \Lambda \). Dots in Eq. (2) stand for higher-derivative terms. Latin indices \( i \) and \( j \) are contracted using \( \delta_{ij} \).

We require the model to admit a background solution with the metric \( g_{\mu\nu} \) equal to the Minkowski metric \( \eta_{\mu\nu} \) and the scalar fields taking the form

\[ \phi^0 = a \Lambda^2 t, \quad \phi^i = b \Lambda^2 x^i, \]

(4)

for some constants \( a \) and \( b \). For a generic function \( F \), such a solution always exists. In the “unitary gauge” where the Goldstone fields are fixed to their vacuum values (4), the second term in the action (2) gives rise to the following mass term for the metric perturbation \( h_{\mu\nu} \):

\[ L_m = \frac{M_{Pl}^2}{2} \left( m_0^2 h_{00}^2 - m_{ij}^2 h_{ij}^2 + m_i^2 h_{ii}^2 - 2m_0 m_i h_{0i} h_{ii} \right), \]

(5)

where the values of the mass parameters \( m_0 \) are determined by the first and the second derivatives of the function \( F(X, W^{ij}) \) at the vacuum values of its arguments as defined by Eqs. (3) and (4). The overall scale \( m \) of the graviton masses is related to \( \Lambda \) as \( m = \Lambda^2 / M_{Pl} \). The analysis of Ref. [22] implies that \( \Lambda \) plays the role of the cutoff scale of the theory with the action (2).
The residual reparametrization symmetry (1) arises in the unitary gauge as a consequence of the global symmetry $\phi^i \to \phi^i + \xi^i(\phi^0)$ of the covariant action (2). This symmetry implies, in particular, that there is no graviton mass term proportional to $h_{00}^2$.

As is usual in the linearized theory, it is convenient to consider separately the tensor, vector, and scalar metric perturbations (cf. Refs. [20,22]). The tensor modes—transverse traceless gravitational waves $h_T^{ij}$—have a non-zero mass equal to $m_2$ [20]. There are no propagating degrees of freedom in the vector sector [22]. Moreover, the contribution of the mass term (5) in the vector sector has the form of a gauge fixing. Consequently, no modification of gravity arises in the vector sector at the order we are working. Finally, the energy-momentum tensor $\delta T_{\mu\nu}$ induces the following perturbations in the scalar sector:

$$\Psi = \Phi_E,$$

$$\Phi = \phi_E + \frac{m_3^2(3m_4^2 - m_2^2)}{m_3^2 - m_0^2} \frac{1}{\partial_i^2} \frac{\delta T_{00}}{M_{Pl}^2},$$

where $\Psi$ and $\Phi$ are the gauge-invariant scalar potentials defined in a standard way [23], and $\Psi_E$ and $\Phi_E$ are their values in the Einstein theory. The modification of gravity manifests itself in the last term in Eq. (7). There is no vDVZ discontinuity as this term vanishes in the limit when all graviton masses uniformly go to zero.

The extra term in Eq. (7) grows linearly with the distance from the source, indicating the breakdown of the linearized theory. The distance cannot be eliminated by a proper choice of the gauge, as $\Phi$ is the gauge-invariant quantity. However, the Riemann curvature associated with the extra term goes to zero as $1/r$ at large $r$, so the spacetime becomes flat far from the source. (This breakdown of perturbation theory is very different in nature from the seemingly similar problem in the Fierz–Pauli theory [14], where it happens in the vicinity of the source. The close analogue of the phenomenon discussed here is the breakdown of perturbation theory far from the source in the three-dimensional classical Yang–Mills theory.) In the region where the nonstandard term in Eq. (7) is still small, it produces the $r$-independent force, imitating the effect of a halo with the density profile $\propto r^{-1}$.

The analysis of Eq. (7) in the region where it enters the nonlinear regime goes beyond the scope of this Letter. Instead, we chose the masses $m_3$ in such a way that the second term in Eq. (7) vanishes. It is important that this can be achieved by imposing, in addition to (1), the following dilatation symmetry:

$$t \to \Lambda t, \quad x^i \to \Lambda^{-\gamma} x^i,$$

which lead to the cancellation of the second term in Eq. (7) for any $\gamma$. Thus, when the symmetry (8) is imposed, the only modification of gravity at the linearized level is the nonzero mass of the graviton.

The inclusion of higher-derivative terms in the action (2) leads, in general, to the appearance of the dynamical degree of freedom in the scalar sector [22]. This degree of freedom is similar to that present in the ghost condensate model [19]. It has a healthy kinetic term provided the following inequality holds [22]:

$$m_2^2 - \frac{m_4^2}{(m_3^2 - m_2^2)} > 0.$$  

The latter condition is compatible with Eq. (9) and the requirement that the graviton mass is not tachyonic, $m_2 > 0$. The effects related to this degree of freedom are characterized by the huge retardation time $\sim m^{-1}(M_{Pl}/\Lambda)$ [19,24,25]. This time is larger than the current age of the universe for the values of the graviton mass $m$ specified below, so we can consistently neglect these effects.

In the covariant formalism the residual symmetry (8) translates into the following global symmetry of the Goldstone sector: $\phi^0 \to \lambda \phi^0, \phi^i \to \lambda \phi^i$. The action invariant under the symmetries (1) and (8) has the form (2) with the function $F$ depending on the single combination $X^2 W^{ij}$. The case of the ghost condensate [19] emerges in the limit $\gamma \to 0$ and requires a fine-tuning of $F$ to obtain the Minkowski vacuum. The Minkowski vacuum with the scalar vacuum expectation values of the form (4) exists for a general function $F$ if $\gamma = 1/d$, where $d = 3$ is a number of spatial dimensions. For definiteness, in what follows we consider the case $F = F(X^{1/3} W^{ij})$.

**Cosmological solutions.**—The spatially flat homogeneous cosmological ansatz is

$$ds^2 = a^2(\eta)(d\eta^2 - dx_i^2),$$

$$\phi^0 = \phi(\eta), \quad \phi^i = \Lambda^2 x^i.$$  

In what follows, we assume that the rate of the expansion is much smaller than the energy scale $\Lambda$, so one can neglect higher-derivative terms in the action (2). For simplicity, let us also assume that the function $F$ depends only on the combination $Z = X^{1/3} W^{ij} \delta_{ij}$. The Einstein equations are reduced to the Friedmann equation:

$$\left(\frac{\dot{a}}{a}\right)^2 = \frac{1}{3M_{Pl}^2} \left(\rho_m + \frac{2}{3} \Lambda^4 F(Z) Z - \Lambda^4 F(Z)\right),$$

where $\rho_m$ is the energy density of matter, and the field equation for $\phi^0$ is

$$\partial_\eta (a^3 F'(Z) WX^{-1/6}) = 0.$$  

Equation (14) implies $Z = \text{const}$ or, equivalently, $\phi^0 \propto \int d\eta a^4(\eta)$. Then Eq. (13) takes the form of the standard Friedmann equation with the value of the cosmological constant determined by the value of $Z$, i.e., by the initial conditions in the Goldstone sector. Note that these initial...
conditions may be different in different regions of space. Therefore, this model is an example of the setup where de Sitter solutions with different expansion rates exist for any value of the vacuum energy. This property is a welcome feature for the application of the weak anthropic principle [26] to the cosmological constant problem.

To summarize, we have constructed a consistent model where gravitational waves are massive, while linearized equations for the metric perturbations in the scalar and vector sectors, as well as spatially flat cosmological solutions, are the same as in the Einstein theory. In this model, the tests of (linear) gravity based on the solar system and Cavendish-type experiments [27] are automatically satisfied, while the main constraints are coming from the emission and/or propagation of gravitational waves.

Relic gravitational waves.—Observations of the slow down of the orbital motion in binary pulsar systems [28] imply that the mass of the gravitational waves cannot be larger than the frequency of the waves emitted by these systems. The latter is determined by the period of the orbital motion which is of order 10 h, implying the following limit on the graviton mass:

\[
\frac{m_g^2}{2\pi} = \nu_2 \equiv 3 \times 10^{-5} \text{ Hz} = (10^{15} \text{ cm})^{-1}.
\]

Let us estimate the cosmological abundance of relic gravitons. For this purpose, we consider the transverse traceless perturbation of the metric \( h_{ij} \). The quadratic action for \( h_{ij} \) in the expanding universe takes the following form:

\[
M_p^2 \int d^3 \kappa \eta a^2(\eta) (\dot{h}_{ij}^2 - \left( \partial_\eta h_{ij}\right)^2 - m_g^2 a^2(\eta) h_{ij}^2).
\]

This has a form of the action for a minimally coupled massive scalar field. Therefore, gravitons in our model are produced efficiently during inflation (cf. Ref. [29]).

To be concrete, consider a scenario where the Hubble parameter \( H_i \) is constant during inflation. This scenario may be realized, for instance, in hybrid models of inflation [30]. First, we need to check that the phenomenologically relevant values of parameters correspond to the regime below the cutoff scale of the effective theory, i.e., \( H_i \ll \Lambda \). For the energy scale of inflation \( E_i \sim \sqrt{H_i M_p^2} \), this implies

\[
E_i < m_g^{1/4} M_p^{3/4} = 10^7 \text{GeV} (m_g^2 \times 10^{15} \text{ cm})^{1/4}.
\]

This value is high enough to allow for a successful baryogenesis even for graviton masses of the order of the current Hubble scale.

Consider now the production of massive gravitons. Assuming the above scenario of inflation, the perturbation spectrum for the massive gravitons is that for the minimally coupled massive scalar field in the de Sitter space [31],

\[
\langle h_{ij}^2 \rangle \approx \frac{1}{4 \pi^2} \left( \frac{H_i}{M_p^4} \right)^2 \int \frac{dk}{k} \left( \frac{k}{H_i} \right)^{2m_g^2/3H_i^2}.
\]

Superhorizon metric fluctuations remain frozen until the Hubble factor becomes smaller than the graviton mass, when they start to oscillate with the amplitude decreasing as \( a^{-3/2} \). The energy density in massive gravitons at the beginning of oscillations is of order

\[
\rho_o \sim M_p^2 m_g^2 \langle h_{ij}^2 \rangle \approx \frac{3H_i^4}{8\pi^2},
\]

where we integrated in Eq. (18) over the modes longer than the horizon. Today, the fraction of the energy density in the massive gravitational waves is

\[
\Omega_g = \frac{\rho_o}{\varepsilon_o \rho_c} = \frac{\rho_o}{\varepsilon_o \rho_c} \left( \frac{H_o}{H_e} \right)^{3/2},
\]

where \( \varepsilon_o \) is the redshift at the start of oscillations, \( H_o \sim m_g^2 \) is the Hubble parameter at that time, \( H_e = 0.4 \times 10^{-12} \text{ s}^{-1} \) is the Hubble parameter at the matter/radiation equality, and \( \varepsilon_e = 3200 \) is the corresponding redshift. Combining all the factors together, one gets

\[
\Omega_g \sim 3 \times 10^3 (m_g^2 \times 10^{15} \text{ cm})^{1/2} \left( \frac{H_i}{\Lambda} \right)^4.
\]

This estimate assumes that the number of \( e \) foldings during inflation is large, \( \ln N_e > H_i^2/m_g^2 \), which is quite natural in the model of inflation considered here.

According to Eq. (21), the massive gravitons are produced efficiently enough to comprise all of the cold dark matter, provided the value of the Hubble parameter during inflation is about 1 order of magnitude below the scale \( \Lambda \). We find it encouraging that one obtains \( \Omega_g \sim 1 \) when the initial energy density in the metric perturbations is close to the cutoff scale, \( \rho_c^{1/4} \sim \Lambda \). This suggests that other mechanisms of production unrelated to inflation (e.g., similar to those invoked for the axion or Polonyi fields) may naturally lead to the same result, \( \Omega_g \sim 1 \).

The produced gravitons may cluster in galaxies. To account for the dark matter in galactic halos, the graviton mass should satisfy \( (mv)^{-1} \leq 1 \text{ kpc} \sim 3 \times 10^{21} \text{ cm} \), where \( v \sim 10^{-3} \) is a typical velocity in the halo.

Detection.—Let us now briefly describe potential observational signatures of the above scenario. Note first that, at distances shorter than the wavelength, the effect of a transverse traceless gravitational wave on test massive particles in Newtonian approximation is described by the acceleration \( h_{ij}x^i/2 \) (see, e.g., Ref. [32] for a review). The same is true for massive gravitational waves, the only difference being that the wavelengths are longer in the nonrelativistic case, so the Newtonian description works for the larger range of distances. Thus, the nonrelativistic waves act on the detector in the same way as massless waves of the same frequency.

Let us estimate the amplitude of the gravitational waves, assuming that they comprise all of the dark matter in the halo of our galaxy. The energy density in nonrelativistic gravitational waves is of order \( M_p^2 m_g^2 h_{ij}^2 \). Equating this to
the local halo density, one gets

\[ \langle h_\nu \rangle \sim 10^{-10} \left( \frac{3 \times 10^{-5}}{v_\nu} \right) \, \text{Hz}. \]  

(22)

At the frequencies $10^{-6}$–$10^{-5}$ Hz, this value is well above the expected sensitivity of the LISA detector [33]. Note that in the close frequency range $10^{-9}$–$10^{-7}$ Hz there is a restrictive bound [34] at the level $\Omega_g < 10^{-9}$ on the stochastic background of the gravitational waves coming from the timing of the millisecond pulsars [35]. So, it is possible that our scenario can be tested by the reanalysis of existing data on the pulsar timing.

The relic abundance of gravitons may depend on both the specific inflationary model and the details of the (unknown) UV completion of massive gravity. In general, massive gravitons may not comprise the whole of the CDM in the galaxy halos. It is important that the expected LISA sensitivity allows us to detect the presence of massive gravitons at the significantly lower level than in Eq. (22).

Concluding remarks.—In this Letter, we limited ourselves to a specific choice of the parameters [graviton masses and the constant $\gamma$ entering Eq. (8)] such that there is no modification of the Newton potential at the linear level, and the cosmological evolution remains standard. We also did not consider possible nonlinear effects, which may become a necessity with different choices of the parameters. A number of interesting questions is related to these effects, including the limits on graviton masses, clustering of massive gravitons in haloes, and the proper modifications of Eqs. (13) and (14) to account for the direct coupling between Goldstone fields and gravitons. We expect, however, that our main conclusions—that gravitons may have large masses and may be produced with cosmologically significant abundance—are generic in this class of models. In the relevant range of parameters, a specific signature of the gravitons with nonzero mass is a strong monochromatic signal in the detectors of gravitational waves. An independent measurement of the graviton mass may be performed at future gravitational wave detectors (for a review, see, e.g., [36]) operating at higher frequencies by testing the delay between the electromagnetic and gravitational signals from a distant supernova explosion.

We thank M. Maggiore, R. Rattazzi, V. Rubakov, M. Sazhin, and M. Shaposhnikov for useful discussions. S. L. D. thanks ULB (Bruxelles) and SPPhT (Saclay), where part of this work was done, for warm hospitality. The work of P. G. T. is supported by IISN, Belgian Science Policy (under Contract No. IAP V/27).
