\textbf{Abstract}

We calculate the averaged equation of state of the dark energy and the angular scale of the acoustic oscillation from the BOOMERANG and WMAP data on the cosmic microwave background (CMB) to constrain the holographic dark energy model recently proposed by Li. We find that only the phantom-like holographic dark energy survives the cosmological tests. This is, however, inconsistent with the positive energy condition implicitly assumed in constructing Li’s model. Therefore the model is ruled out by the present CMB data. Moreover, the constraints on the phantom-like holographic dark energy derived from the angular acoustic scale and from the integrated Sach-Wolfe (ISW) effect are found to be consistent with each other. Some aspect about the saturation of the cosmic holographic bound is also discussed.

1 Introduction and Conclusion

The idea of holographic principle for strong gravity systems inspired from the area law of Bekenstein-Hawking’s entropy has been widely accepted after the success of the AdS/CFT correspondence. The extension of the holographic principle to more general cases such as the FRW background was first proposed by Fischler and Susskind [1], and completed later on by Bousso [2] in the name of covariant entropy bound. It states that the entropy on the non-expanding light-sheet of a surface $B$ will be bounded by the area of $B$. The intuitive picture behind the statement is that the more entropy we put in a region, the more we increase the energy in it. This in turn will curve the passing-by light ray more and eventually a caustic will form and terminate the light-sheet. The maximal entropy one can have is for the whole region to collapse into a black hole, and thus the entropy is bounded by Bekenstein-Hawking’s area law.

It is then intriguing if the generic covariant entropy bound can be used to constrain cosmological models. Recently, a viable model for the dark energy based on the holographic principle has been proposed by Li [4] (see also the follow-up in [5]). The model seems to comply with the recent observation that the Universe is accelerating [6]. Therefore, it deserves further check to see whether its prediction is also consistent with the recent data [7, 8] on the cosmic microwave background (CMB) anisotropies. As far as we can see, the recent CMB data has become precise enough to constrain the model to some extent.

In this note, we check the so called HCDM (holographic dark energy plus cold dark matter) model by first calculating the angular scale of the acoustic oscillation on the last scattering surface, and then estimating the integrated Sach-Wolfe (ISW) effect characterized by the weighted equation of state. We find that the recent cosmological data prefer phantom-like holographic dark energy. Similar conclusion was also arrived in the first reference in [5] by examining the luminosity distance of the SN Ia data [6]. Unfortunately, the phantom-like dark energy is inconsistent with the positive energy condition (PEC), which must be satisfied to derive Li’s holographic bound. We must then conclude that the HCDM is ruled out by the CMB data from our analysis. Moreover, the phantom-like HCDM will also violate the generalized 2nd law of thermodynamics (GSL) if we assume that the later universe is dominated by the holographic dark energy whose entropy is bounded by the area law.

\[1\] Here, one must assume the matter associated with it obeys the positive energy condition. In contrast, the phantom-like dark matter/energy violates the positive energy condition and does not have to obey the holographic bound.
In the literature, when the holographic principle is exploited to build HCDM models, there is always an implicit assumption, which we call “maximal darkness conjecture” (MDC), that the holographic bound is saturated so that there is a definite UV-IR connection. However, there is no strong argument that our universe is right on the verge of saturating the holographic bound. The area law conjectured in [1, 2] is used in the naive version of MDC. It leads to the conclusion that the nature is filled with the maximal amount of dark matter or dark energy so that our universe has become a black hole. In this form, the conjecture is hardly justifiable and does not yield a realistic model as will be discussed in the next section. To have a more realistic HCDM model, Li uses the area law suggested in [9]. This leads to a new bound related to Jean’s instability. Although the new bound is less restrictive, it still implies that our Universe is on the verge of becoming a black hole. This is again hard to justify. Despite of the problem, the resultant model seems to be viable.

From the above discussion it is clear that there may still be space to further relax the MDC so that a more realistic non-phantom like dark energy model based on holographic principle could emerge. A most intuitive evidence that the MDC could be wrong is that there is no single evidence that we are approaching a black hole singularity anytime soon. However, we will leave the justification/falsification for MDC to future works and focus on the cosmological test of the HCDM models.

In the next section we will review the HCDM models and give some details to make the above discussions more concrete. Especially the requirement of PEC in constructing HCDM is noted. In the last section we will provide our analysis of the CMB constraints on the HCDM model, we find that the CMB data rule out HCDM since our result favors the phantom-like dark energy which violates PEC. Moreover, the conclusions from ISW effect and the acoustic oscillation of CMB power spectrum are consistent with each other for the model.

2 The model

The basic idea of the holographic dark energy is that we can use the saturation of the entropy bound to relate the unknown UV scale $\Lambda$ to some known cosmological scale, so that we can have a viable formula for the dark energy which is of quantum gravity origin characterized by $\Lambda$. Naively one may choose the covariant entropy bound to get the UV-IR connection, however, this implies that the whole universe will be dominated by black hole states. In other words, this means that the back-reaction caused by the
quantum dark energy will be too large for classical gravity to be reliable.

The authors in [9] proposed a more restrictive bound

\[ L \gtrsim G_N E_\Lambda \implies L\Lambda^2 \lesssim M_p, \tag{1} \]

where \( L \) is the size of the system, \( E_\Lambda = L^3 \Lambda^4 \) and \( 8\pi G_N = 1/M_p^2 \). The above argument bases on the bending of light-rays due to the gravitational energy \( \rho + p \). One must assume that the vacuum energy does obey the positive energy condition (PEC), i.e., \( \rho_\Lambda + p_\Lambda > 0 \). Otherwise, the vacuum energy will unbind the light-rays, and contradicts the statement that more entropy implies more energy. This then rules out the cosmological constant and the phantom-like dark energy.

Equation (1) means that no gravitational collapse will be induced by the vacuum energy so that we can still trust classical gravity. From UV-IR connection, the saturation of the bound (1) implies that the vacuum energy density is given by

\[ \rho_\Lambda = 3c^2 M_p^2 L^{-2}. \tag{2} \]

Here, the parameter \( c \) characterizes the degree that the Jeans bound is saturated. As discussed in the last section, there is an implicit assumption in the “maximal darkness conjecture” (MDC) where the proposed bound is saturated so that one can derive the UV-IR connection. The MDC is at work if \( c \) is of order one, and this turns out to be the case from data constraints.

Although the form of equation (2) seems quite universal and may apply to any system such as the galaxy clusters besides the universe, equation (1) suggests that for a fixed UV-cutoff \( \Lambda \) the bound is harder to be saturated in smaller systems. Therefore we will assume it is saturated only for the cosmic scale with a UV-cutoff \( \Lambda \) of quantum gravity origin.

We should choose an appropriate IR scale \( L \) to make the model compatible with the observed dark energy. If \( L \) is the Hubble horizon, namely \( L \sim 1/H \), then this result is quite suggestive since it agrees with what we observe today, i.e. the Universe is dominated by the dark energy so that \( \rho_\Lambda \approx \rho_c \equiv 3M_p^2 H^2 \). Moreover, the entropy of the dark energy \( \rho_\Lambda \) is

\[ S_J = (S_{CEB})^{\frac{2}{3}} \tag{3} \]

which is below Bousso’s covariant entropy bound \( S_{CEB} \). In contrast, saturating Bousso’s bound will yield \( \rho_\Lambda \approx (M_p^2 H)^{\frac{3}{4}} \), which is inconsistent with the observational data today unless some extreme fine-tuning is done.

\(^2\text{This can be seen by examining the Raychaudhuri equation. The same PEC is imposed when deriving the covariant entropy bound \([9]\).}\)
We know that today’s Universe is accelerating according to SN Ia data [6]. It then requires that \( w_\Lambda \equiv p_\Lambda/\rho_\Lambda < -1/3 \). It is easy to see that the naive choice of \( L \sim 1/H \) will give \( w_\Lambda = 0 \) [10]. To have a model consistent with the previous condition, Li [4] proposed that one should adopt the covariant entropy bound and choose \( L \) to be either the particle horizon \( R_H(t) = a(t) \int_0^t \frac{dt'}{a(t')} \) or the event horizon \( R_h(t) = a(t) \int_t^\infty \frac{dt'}{a(t')} \). Making use of energy conservation, we then obtain the changing rate of the horizon size

\[
\frac{dR_{H,h}}{da} = \frac{R_{H,h}}{a} \left( 1 \pm \sqrt{\frac{\Omega_\Lambda}{c^2}} \right),
\]

and the equation of state

\[
w_\Lambda = -\frac{1}{3} \left( 1 \pm 2 \sqrt{\frac{\Omega_\Lambda}{c^2}} \right).
\]

Here \( a \) is the scale factor of the Robertson-Walker metric, and the upper(lower) sign is for \( L = R_H(R_h) \). It is then obvious that using \( R_H \) as \( L \) will not lead to an accelerating Universe.

Although using \( R_h \) as the cosmic scale can give rise to an accelerating Universe, it is phantom-like today, i.e., \( w_\Lambda^0 < -1 \) if \( c^2 < \Omega_\Lambda^0 \approx 0.7 \). As a result, both the GSL and PEC will be violated in this model. The violation of GSL can be seen explicitly by calculating the cosmic entropy associated with the dark energy is \( S_f = (\pi R_h^2)^{3/4} \) as given in [3]. Since \( \Omega_\Lambda \) approaches 1 in the later Universe, we must require \( c^2 \geq 1 \) so that \( dR_h/da \geq 0 \) all the time and the GSL and PEC are always obeyed. We need the PEC to derive the bound of energy density [2], which is the basis of the HCDM model. Therefore, it does not make sense to consider phantom-like HCDM model.

### 3 The constraints from CMB and SN Ia data

Now we would like to use the CMB data to further constrain the HCDM model parameter \( c \). Instead of doing the global fitting to the CMB data, we will choose two relevant parameters synthesizing the essence of CMB physics, namely, the acoustic scale characterizing the acoustic oscillations in the recombination epoch, and the energy density weighted equation of state characterizing the ISW effect.

The Friedmann equation in the flat Robertson-Walker metric is given by

\[
\left( \frac{da}{d\eta} \right)^2 = \frac{c^2 a^2}{(H_0 \eta)^2} + a \Omega_m^0 + \Omega_r^0,
\]
which we will solve with the initial condition

\[ a(\eta_0) = 1 \]  

(7)

to unfold the cosmology. In the above equations we have re-scaled the co-moving time by today’s Hubble constant \( H_0 \), and the conformal time \( \eta \equiv \int_0^\infty dt'/a(t') \) is different from the conventional one. \( \Omega_m^0 \) and \( \Omega_r^0 \) are the ratio of energy density of non-relativistic and relativistic matters to the critical density today. Their values are 0.27 and \( 8.23727 \times 10^{-5} \), respectively, according to [6] and [8]. Note that relativistic matters here include both photon and neutrino. The same equation can also be expressed in the following form:

\[
\frac{d\Omega_\Lambda(x)}{dx} = \Omega_\Lambda(x) \left\{ 1 - \Omega_\Lambda(x) \right\} \left\{ 1 + \frac{2\sqrt{\Omega_\Lambda(x)}}{c} + \frac{\rho_r^0}{\rho_m^0 e^x + \rho_r^0} \right\}.
\]  

(8)

Here, \( \rho_m^0 \) and \( \rho_r^0 \) are the energy density of non-relativistic and relativistic matters today, and \( x = \ln a \). If we neglect \( \rho_r^0 \) (or \( \rho_m^0 \)), then the equation can be solved as in [4]. Otherwise one generally needs to solve the equation numerically. Since we are interested in the angular acoustic scale for which the radiation dominated epoch is also relevant, we must keep \( \Omega_r \) and evolve the equation (6) numerically.

To put constraints on HCDM, we first evaluate the acoustic oscillation in the CMB power spectrum of anisotropies. It occurred in the tightly coupled photon-baryon plasma before the recombination epoch, and then modulated the anisotropy of CMB spectrum observed today. The scale is characterized by [11]

\[
\ell_A = \frac{d_*}{h_s} = \pi \frac{\eta_0 - \eta_{\text{dec}}}{\int_{\eta_{\text{bb}}}^{\eta_0} c_s d\eta}.
\]  

(9)

Here, \( d_* \) denotes the co-moving distance to the last scattering surface, \( h_s \) the sound horizon right before the decoupling epoch, \( c_s \) the sound speed, and \( \eta_{\text{bb}} \) the co-moving time at the big-bang. Note that both \( d_* \) and \( h_s \) are affected by the presence of dark energy, as well as the matter and baryon density. The sound speed is given by

\[
c_s = \frac{1}{\sqrt{3(1 + R)}}.
\]  

(10)

with

\[
R \equiv \frac{3\rho_b}{4\rho_\gamma} \approx 30366 \left( \frac{T_\gamma^0}{2.725 K} \right)^{-4} \frac{\Omega_b^0 h^2}{1 + z}
\]  

(11)

where we have set \( H_0 = 100h \) km s\(^{-1}\) Mpc\(^{-1}\). Apparently, the baryon-photon energy density ratio \( R \) determines the “stiffness constant” in the acoustic oscillation of CMB.
On the other hand, the acoustic scale $\ell_A$ can be extracted by the locations of the acoustic peaks, which can be read out from the CMB power spectrum of anisotropy either theoretically \cite{12} or by an empirical formula \cite{13}

$$\ell_m = \ell_A(m - \varphi_m) \quad (12)$$

where $\ell_m$ denotes the angular position of the $m$-th acoustic peak. As explicitly shown in \cite{12} the acoustic oscillations for large $\ell$ are dressed by the dragging of the baryon-photon plasma and the Doppler shift due to the primordial gravitational bumps. This is why the empirical formula is a more direct way to extract the acoustic scale \cite{13}. Using simulations, the authors have shown that the shift of the 3rd peak is relatively insensitive to the cosmological parameters and the best fit to its phase shift $\varphi_3$ is 0.341.

From the fitting of the BOOMERANG data at the year 2002 \cite{7} they find that

$$\ell_A^{BOOM} = 316 \pm 8 \quad (13)$$

with the following cosmological parameters: $h = 0.65$ and $z_{dec} = 1100$, the matter density $\Omega_0^m = 0.3$ which includes the baryon density $\Omega_0^b = 0.05$, and $\Omega_0^\Lambda = 0.7$. We would like to emphasize that this value of $\ell_A^{BOOM}$ has been extracted from a model-insensitive simulation \cite{13}.

On the other hand, the 1st year WMAP data yield a value \cite{8}

$$\ell_A^{WMAP} = 301 \pm 1 \quad (14)$$

by fitting the underlying $\Lambda$CDM model with the following cosmological parameters: $h = 0.71$ and $z_{dec} = 1089$, $\Omega_0^0 = 0.27$ which include the baryon density $\Omega_0^b = 0.044$, as well as $\Omega_0^\Lambda = 0.73$. Although the WMAP data is more up to date, no model-insensitive extraction of the acoustic scale $\ell_A$ has been done. To have a double check on HCDM, we will use both data sets to constrain HCDM.

Using the cosmological parameters extracted from the WMAP data, we calculate the $\ell_A$ for HCDM models, and the result is presented in Fig. 1. The result shows that $\ell_A = 292 \pm 7$ for $c = 1$ which falls out of the window (the gray region) allowed by the WMAP data based on the underlying $\Lambda$CDM model and the GSL for the holographic entropy. Since the allowed values for $\ell_A^{WMAP}$ is based on the underlying $\Lambda$CDM model, it cannot serve as a model-independent constraint. Our results derived from the WMAP data simply indicate how much the prediction by HCDM deviates from that by $\Lambda$CDM. Apparently, the deviation is quite significant for the non-phantom HCDM.

Similarly the outcomes from the constraints by the BOOMERANG are displayed in Fig. 2.
Figure 1: The solid curve depicts the dependence of $\ell_A$ on $c$ with $\Omega_r^0$ and $\Omega_m^0$ given by WMAP data. The shaded region is the window allowed by both the PEC/GSL and WMAP data. The dotted and the dashed curves below and above the solid one are obtained by taking into account the uncertainty of $\Omega_\Lambda^0$, as indicated in the graph.

The results shows that $\ell_A = 302$ for $c = 1$ which still falls out of the window of BOOMERANG and GSL (the gray region) even though the window here is wider than the previous one from the WMAP data. Since $\ell_A^{BOOM}$ for the BOOMERANG data is extracted from a model-insensitive method, it can serves as a model-independent constraint for HCDM. In summary, the above analyses of the acoustic angular scale from WMAP and BOOMERANG lead to the consistent conclusion that the HCDM models are disfavored.

The next thing we would like to do is to check the constraint derived from the integrated Sach-Wolfe (ISW) effect, which arises from the time-varying Newtonian potential (thus $w_\Lambda \neq 0$) after the last scattering surface. The ISW effect basically measures the
Figure 2: The solid curve depicts the dependence of $\ell_A$ on $c$ with $\Omega_r^0$ and $\Omega_m^0$ given by Boomerang data. The shaded region is the window allowed by both the PEC/GSL and Boomerang data. Unlike the WMAP, there is no estimate of error for the cosmological parameters in BOOMERANG.

breakdown of matter domination at early times (in the radiation regime) and at late times (in the dark energy regime). To characterize the effect from the time-varying $w_\Lambda$ of HCDM, it is useful to define the $\Omega_\Lambda$-weighted value

$$\langle w_\Lambda \rangle = \frac{\int_{\eta_0}^{\eta_{\text{dec}}} d\eta \Omega_\Lambda(\eta) w_\Lambda(\eta)}{\int_{\eta_0}^{\eta_{\text{dec}}} d\eta \Omega_\Lambda(\eta)}$$

(15)

where $\Omega_\Lambda \equiv \rho_\Lambda/(3M_p^2H^2)$ is the ratio of the dark energy density to the critical density of the universe. $\eta_0$ and $\eta_{\text{dec}}$ are the conformal time at present and at the last scattering surface.

There is a constraint from the SN Ia data showing that $\langle w_\Lambda \rangle$ should be less than $-0.75$. However, a study on the generic quintessence (GQ) shows that the constraint should be more restrictive due to the suppression of the growth of the matter fluctuation $\delta$ by the dark energy. The suppression effect is governed by the equation of
motion
\[ \frac{d^2\delta}{d\eta^2} + a\mathcal{H} \frac{d\delta}{d\eta} - \frac{3}{2} a^2 \mathcal{H}^2 \Omega_m \delta = 0, \]
where \( \mathcal{H} \equiv H/H_0 \) would inevitably admit the influence of the dark energy. Compared with the \( \Lambda \)CDM model, the CMB anisotropy power spectrum from GQ models has a significant excess at \( \ell \sim 100 \) when normalized to the Cosmic Background Explorer (COBE) data. In order to keep the suppression stable at about 30\% level, the averaged equation of state \( \langle w_\Lambda \rangle \) must be less than \(-0.9\). An accurate determination would require computing small-scale matter perturbations as well as performing a maximum-likelihood fitting to the existing CMB anisotropy data. However, the constraint derived from the evolution of the growth factor under the influence of the ISW effect is more severe than the constraint from SN Ia data, and is good enough to serve as a fast tool to test any specific model of dark energy such as HCDM here.

Accordingly, we calculate \( \langle w_\Lambda \rangle \) for HCDM by using the different sets of cosmological parameters adopted by the WMAP and BOOMERANG data respectively. The results are shown in Fig. 3 for WMAP and in Fig. 4 for BOOMERANG.

First we note that \( \langle w_\Lambda \rangle \) is always larger than \( w_\Lambda^0 \). This provides a non-trivial constraint that the HCDM models is less phantom on average than it is now and has more-suppression of matter growth. Meanwhile, we find that the constraint for \( \langle w_\Lambda \rangle < -0.9 \) is satisfied only if \( c \lesssim 0.7 \) both for BOOMERANG and WMAP data. Again, the HCDM models are disfavored. Since the constraint \( \langle w_\Lambda \rangle < -0.9 \) is derived from the generic quintessence scenario [15], it insures that the result is model-insensitive. Also note that the value of \( \langle w_\Lambda \rangle \) at \( c = 1 \) is about \(-0.75\), which is consistent with the constraint from the SN Ia data [6] but is ruled out by the ISW effect to guarantee a proper suppression of the growth of matter fluctuations. Therefore, it provide a more stringent constraint.

Moreover, we see that the same criterion \( c \lesssim 0.7 \) appears in constraining the ISW effect as well as the acoustic angular scale of CMB. This coincidence indicates that the two cosmological tests on \( \ell_A \) and \( \langle w_\Lambda \rangle \) derived from the CMB data are consistent and favors the phantom-like HCDM model. It would be interesting to understand why there is such corelation between the two tests.

Our analysis shows that there is a discrepancy between the observational data of CMB and the theoretical preference of HCDM. Though a phantom-like dark energy is by its own a viable model, it is inconsistent with the implicit PEC assumption in deriving HCDM and should be ruled out from the point of view of holographic principle. We thus conclude that the HCDM based on the UV-IR relations [11] and [2] is ruled
out by present CMB data.

Since the argument for holographic principle is quite general, and we expect that it plays a crucial role in defining the dark energy. Hence, the inconsistency shown in this paper indicates that there may have some subtlety in implementing MDC. Knowing that our universe is not as dark as inside a black hole, we have abandoned the old covariant entropy bound and adopted the bound on Jeans instability, which lead us to the HCDM model. It is quite possible that our universe is not even dark enough to saturate Jeans’ bound, and we may need a new criterion to relate the UV and IR physics in implementing MDC based on the holographic principle.
