revised: 19 January 2006

Abstract. The group of local unitary transformations acts on the space of $n$-qubit pure states, decomposing it into orbits. In a previous paper we proved that a product of singlet states (together with an unentangled qubit for a system with an odd number of qubits) achieves the smallest possible orbit dimension, equal to $3n/2$ for $n$ even and $(3n + 1)/2$ for $n$ odd, where $n$ is the number of qubits. In this paper we show that any state with minimum orbit dimension must be of this form, and furthermore, such states are classified up to local unitary equivalence by the sets of pairs of qubits entangled in singlets.

1 Introduction

Quantum entanglement has been identified as an important resource for quantum computing, quantum communication, and other applications [1, 2]. A fundamental theoretical problem is to understand the types of entanglement that composite quantum systems can achieve.

Defining entanglement types as equivalence classes of quantum states under local unitary (LU) equivalence is perhaps the most natural way to proceed in classifying entanglement [3, 4]. The group of LU transformations acts on the space of quantum states, partitioning it into LU orbits. Each orbit is a collection of locally equivalent quantum states that forms a differentiable manifold with a certain dimension.

The classification of entanglement types has turned out to be a difficult problem. Most of the progress in understanding multipartite entanglement has been for systems of only two or three qubits [3, 5, 6]. Few results exist concerning the classification of $n$-qubit entanglement types for arbitrary $n$.

A promising approach to the difficult problem of characterizing entanglement types is to break the problem into two parts. First, identify the possible dimensions of LU orbits in the state space. Then, identify the orbits that have each possible dimension. In [3], the present authors addressed the first part of this program by identifying the allowable range of orbit dimensions for $n$-qubit quantum states to be $3n/2$ to $3n$ for even $n$ and $(3n + 1)/2$ to $3n$ for odd $n$. The present paper begins the second part of the program by completely identifying all orbits (entanglement types) with minimum dimension.
In this paper, we identify all $n$-qubit entanglement types that have minimum orbit dimension. States that have the minimum orbit dimension are, in some sense, the “rarest” quantum states. We show that the only quantum states to achieve minimum orbit dimension are tensor products of singlet states (with a single unentangled qubit for $n$ odd) and their LU equivalents. This suggests a special role for the 2-qubit singlet state in the theory of $n$-qubit quantum entanglement.

## 2 Notation and previous results

In this section we establish notation, some definitions, and state some results from our previous paper [8] needed for the present paper. For the convenience of the reader, we give a list (Appendix A) of equation and statement numbers in the present paper with their matching numbers in [8].

Let $|0\rangle, |1\rangle$ denote the standard computational basis for $\mathbb{C}^2$ and write $|i_1i_2\ldots i_n\rangle$ for $|i_1\rangle \otimes |i_2\rangle \otimes \cdots \otimes |i_n\rangle$ in $(\mathbb{C}^2)^\otimes n$. For a multi-index $I = (i_1i_2\ldots i_n)$ with $i_k = 0,1$ for $1 \leq k \leq n$, we will write $|I\rangle$ to denote $|i_1i_2\ldots i_n\rangle$. Let $i_k^c$ denote the bit complement

$$i_k^c = \begin{cases} 
0 & \text{if } i_k = 1 \\
1 & \text{if } i_k = 0 
\end{cases}$$

and let $I_k$ denote the multi-index

$$I_k := (i_1i_2\ldots i_{k-1}i_k^ci_{k+1}\ldots i_n)$$

obtained from $I$ by taking the complement of the $k$th bit for $1 \leq k \leq n$. Similarly, let $I_{kl}$ denote the multi-index

$$I_{kl} := (i_1i_2\ldots i_{k-1}i_k^ci_{k+1}\ldots i_l^ci_l^ci_{l+1}\ldots i_n)$$

obtained from $I$ by taking the complement of the $k$th and $l$th bits for $1 \leq k < l \leq n$.

Let $H = (\mathbb{C}^2)^\otimes n$ denote the Hilbert space for a system of $n$ qubits and let $\mathbb{P}(H)$ denote the projectivization of $H$ which is the state space of the system. We take the local unitary group to be $G = \text{SU}(2)^n$. Its Lie algebra $LG = \text{su}(2)^n$ is the space of $n$-tuples of traceless skew-Hermitian $2 \times 2$ matrices. We choose $A = i\sigma_z = \begin{bmatrix} i & 0 \\
0 & -i \end{bmatrix}$, $B = i\sigma_y = \begin{bmatrix} 0 & 1 \\
-1 & 0 \end{bmatrix}$, and $C = i\sigma_x = \begin{bmatrix} 0 & i \\
i & 0 \end{bmatrix}$ as a basis for $\text{su}(2)$, where $\sigma_x, \sigma_y, \sigma_z$ are the Pauli spin matrices. We define elements $A_k, B_k, C_k$ of $LG$ for $1 \leq k \leq n$ to have $A, B, C$, respectively, in the $k$th coordinate and zero elsewhere.

$$A_k = (0,\ldots,\begin{bmatrix} i & 0 \\
0 & -i \end{bmatrix},0,\ldots,0)$$

$$B_k = (0,\ldots,\begin{bmatrix} 0 & 1 \\
-1 & 0 \end{bmatrix},0,\ldots,0)$$

$$C_k = (0,\ldots,\begin{bmatrix} 0 & i \\
i & 0 \end{bmatrix},0,\ldots,0)$$
Lyons and Walck, Classification of n-qubit states with min. orb. dimension

Given a state vector $|\psi\rangle = \sum c_I |I\rangle$, we have the following.

\[ A_k |\psi\rangle = \sum_I i(-1)^i c_I |I\rangle \quad (1) \]
\[ B_k |\psi\rangle = \sum_I (-1)^i c_{kI} |I\rangle \quad (2) \]
\[ C_k |\psi\rangle = \sum_I ic_{kI} |I\rangle \quad (3) \]

Given a state vector $|\psi\rangle \in H$, we define the $2^n \times (3n+1)$ complex matrix $M$ to be the $(3n+1)$-tuple of column vectors

\[ M = (A_1 |\psi\rangle, B_1 |\psi\rangle, C_1 |\psi\rangle, \ldots, A_n |\psi\rangle, B_n |\psi\rangle, C_n |\psi\rangle, -i |\psi\rangle \}. \quad (4) \]

We view the matrix $M$ and also its column vectors both as real and also as complex via the standard identification

\[ \mathbb{C}^N \leftrightarrow \mathbb{R}^{2N} \]
\[ (z_1, z_2, \ldots, z_N) \leftrightarrow (a_1, b_1, a_2, b_2, \ldots, a_N, b_N) \quad (5) \]

where $z_j = a_j + ib_j$ for $1 \leq j \leq N$. The real rank of $M$ gives the dimension of the $G$ orbit of a state.

**Proposition 2.1.** Orbit dimension as rank of $M$: Let $x \in \mathbb{P}(H)$ be a state, let $|\psi\rangle$ be a Hilbert space representative for $x$, and let $M$ be the associated matrix constructed from the coordinates of $|\psi\rangle$ as described above. Then we have

\[ \text{rank}_R M = \dim O_x + 1. \]

We denote by $C$ the set

\[ C = \{ A_1 |\psi\rangle, B_1 |\psi\rangle, C_1 |\psi\rangle, \ldots, A_n |\psi\rangle, B_n |\psi\rangle, C_n |\psi\rangle, -i |\psi\rangle \} \]

of columns of $M$, and for $1 \leq k \leq n$ we define the triple $T_k \subseteq C$ to be the set of vectors

\[ T_k = \{ A_k |\psi\rangle, B_k |\psi\rangle, C_k |\psi\rangle \}. \quad (6) \]

For a subset $B \subseteq C$, we write $\langle B \rangle$ to denote the real span of the column vectors contained in $B$. For convenience we write $\langle T_{i_1}, T_{i_2}, \ldots, T_{i_r} \rangle$ to denote the real span $\langle T_{i_1} \cup T_{i_2} \cup \cdots \cup T_{i_r} \rangle$ of a set of triples. We have the following facts about the dimensions of spans of sets of triples.

**Proposition 2.2.** Let $T_k = \{ A_k |\psi\rangle, B_k |\psi\rangle, C_k |\psi\rangle \}$ be a triple of columns of $M$. The three vectors in the triple are orthogonal when viewed as real vectors.

**Proposition 2.3.** Main orthogonality proposition: Suppose that

\[ \dim \langle T_{j_1}, T_{j_2}, \ldots, T_{j_m} \rangle < 3m \]

for some $1 \leq j_1 < j_2 < \cdots < j_m \leq n$. Then there is a nonempty subset $K \subseteq \{ j_1, j_2, \ldots, j_m \}$ containing an even number of elements such that there are two orthogonal vectors $|\zeta_k\rangle, |\eta_k\rangle$ in $\langle T_k \rangle$, both of which are orthogonal to $-i |\psi\rangle$, $A_j |\psi\rangle, B_j |\psi\rangle$ and to $C_j |\psi\rangle$ for all $k \in K, j \notin K$.

More can be said about a pair of triples which together span fewer than five dimensions.
Lemma 2.4. Suppose that for some $1 \leq l < l' \leq n$ we have $A_l |\psi\rangle = A_{l'} |\psi\rangle$ and $C_l |\psi\rangle = C_{l'} |\psi\rangle$. Then $A_k |\psi\rangle$, $B_k |\psi\rangle$, and $C_k |\psi\rangle$ are each orthogonal to $-i |\psi\rangle$ and to $A_j |\psi\rangle$, $B_j |\psi\rangle$, $C_j |\psi\rangle$ for all $k \in \{l,l'\}$, $j \notin \{l,l'\}$.

Proposition 2.5. Generalization of 2.4: Suppose that $\dim \langle T_1, T_1' \rangle \leq 4$ for some $1 \leq l < l' \leq n$. Then $A_k |\psi\rangle$, $B_k |\psi\rangle$, and $C_k |\psi\rangle$ are each orthogonal to $-i |\psi\rangle$ and to $A_j |\psi\rangle$, $B_j |\psi\rangle$, $C_j |\psi\rangle$ for all $k \in \{l,l'\}$, $j \notin \{l,l'\}$.

We use propositions 2.2, 2.3 and 2.5 to establish the lower bound for the rank of $M$, and therefore also for orbit dimension.

Proposition 2.6. Minimum rank of $M$: Let $|\psi\rangle \in H$ be a state vector, and let $M$ be the matrix associated to $|\psi\rangle$. We have

$$\text{rank}_R M \geq \left\{ \begin{array}{ll} \frac{3n}{2} + 1 & \text{if } n \text{ even} \\ \frac{3n}{2} & \text{if } n \text{ odd} \end{array} \right.$$

A product of singlets (together with an unentangled qubit for $n$ odd) achieves the lower bound established in 2.6. This establishes the minimum orbit dimension.

Theorem 2.7. For the local unitary group action on state space for $n$ qubits, the smallest orbit dimension is

$$\min \{ \dim \mathcal{O}_x : x \in \mathbb{P}(H) \} = \left\{ \begin{array}{ll} \frac{3n}{2} + 1 & \text{if } n \text{ even} \\ \frac{3n}{2} & \text{if } n \text{ odd} \end{array} \right.$$

This concludes the statements of definitions and results from [8] to be used in the sequel.

3 Further results on ranks of sets of triples

In this section we develop more facts about ranks of sets of triples of the columns of the matrix $M$ associated to an $n$-qubit state vector $|\psi\rangle$ as described in the previous section. These include strengthened versions of 2.6. We begin with a general fact about local unitary invariance.

Proposition 3.1. The dimension of the span of a union of triples with or without the rightmost column $-i |\psi\rangle$ is a local unitary invariant.

Proof. We prove the proposition for the case “with the rightmost column.” The same proof works for the case “without the rightmost column” by making the obvious changes.

Let $T_{j_1}, T_{j_2}, \ldots, T_{j_m}$ be a set of triples of columns of the matrix $M$ associated to the state vector $|\psi\rangle$. Let $U = \prod_{i=1}^m U_i$ be an element of the local unitary group and let $M'$ with triples $T_{i}' = \{A_k U |\psi\rangle, B_k U |\psi\rangle, C_k U |\psi\rangle\}$ be associated to the state $|\psi'\rangle = U |\psi\rangle$. Since $U$ is unitary, the dimension of the span

$$\dim \langle T_{j_1}' \cup T_{j_2}' \cup \ldots \cup T_{j_m}' \cup \{-i |\psi'\rangle\} \rangle$$

is equal to the dimension of the span of the set

$$(*) \quad \bigcup_{i=1}^m \{ U^\dagger A_{j_i} U |\psi\rangle, U^\dagger B_{j_i} U |\psi\rangle, U^\dagger C_{j_i} U |\psi\rangle \} \cup \{-i |\psi\rangle \}.$$
Observe that
\[
U^\dagger A_k U = (0, \ldots, 0, U_k^1 A U_k, 0, \ldots, 0) = (0, \ldots, 0, \text{Ad}(U_k^1)(A), 0, \ldots, 0)
\]
\[
U^\dagger B_k U = (0, \ldots, 0, U_k^1 B U_k, 0, \ldots, 0) = (0, \ldots, 0, \text{Ad}(U_k^1)(B), 0, \ldots, 0)
\]
\[
U^\dagger C_k U = (0, \ldots, 0, U_k^1 C U_k, 0, \ldots, 0) = (0, \ldots, 0, \text{Ad}(U_k^1)(C), 0, \ldots, 0)
\]
where the zeros occur in all but the kth coordinate and \( \text{Ad}: \text{SU}(2) \to \text{SO}(\text{su}(2)) \) denotes the adjoint representation of \( \text{SU}(2) \) on its Lie Algebra. It follows that the span of the set (\( * \)) lies inside the span of the set
\[
(\star\star) \bigcup_{i=1}^{m} \{ A_{j_i} | \psi \rangle, B_{j_i} | \psi \rangle, C_{j_i} | \psi \rangle \} \cup \{ -i | \psi \rangle \}
\]
and hence that
\[
\dim(T_{j_1} \cup T_{j_2} \cup \ldots \cup T_{j_m} \cup \{ -i | \psi \rangle \}) \leq \dim(T_{j_1} \cup T_{j_2} \cup \ldots \cup T_{j_m} \cup \{ -i | \psi \rangle \}).
\]
Reversing the roles of \( | \psi \rangle \) and \( | \psi' \rangle \) yields that the span of the set (\( \star \star \)) lies inside the span of the set (\( * \)), and hence that
\[
\dim(T_{j_1} \cup T_{j_2} \cup \ldots \cup T_{j_m} \cup \{ -i | \psi \rangle \}) \geq \dim(T_{j_1} \cup T_{j_2} \cup \ldots \cup T_{j_m} \cup \{ -i | \psi \rangle \}).
\]
This concludes the proof.

Next we consider the case of two triples which together span five dimensions.

**Proposition 3.2.** Suppose that \( \dim(T_i, T_{i'}) = 5 \) for some \( 1 \leq l \leq l' \leq n \). Then there are four independent vectors \( | \zeta_i \rangle, | \eta_i \rangle \in T_i, | \zeta_{i'} \rangle, | \eta_{i'} \rangle \in T_{i'}, \) which are orthogonal to \( -i | \psi \rangle \) and to \( A_j | \psi \rangle, B_j | \psi \rangle, C_j | \psi \rangle \) for all \( j \not\in \{l, l'\} \).

**Proof.** Applying the main orthogonality proposition \( 2.3 \), the only new claim made in the statement of \( 3.2 \) is that the vectors \( | \zeta_k \rangle, | \eta_k \rangle \in T_k, k \in \{l, l'\} \) are independent. In the proof of \( 2.3 \) there is a unitary transformation \( U: H \to H \) such that
\[
U | \zeta_k \rangle = B_k U | \psi \rangle,
\]
\[
U | \eta_k \rangle = C_k U | \psi \rangle
\]
for \( k \in \{l, l'\} \) and \( A_l U | \psi \rangle \) is collinear with \( A_l U | \psi \rangle \). Since \( \dim(T_l, T_{l'}) = 5 \), the span of \( \{ A_l U | \psi \rangle, B_k U | \psi \rangle, C_k U | \psi \rangle : k = l, l' \} \) is also five dimensional by \( 2.1 \).
Thus the collinearity of \( A_l U | \psi \rangle \) and \( A_l U | \psi \rangle \) implies that \( U | \zeta_l \rangle, U | \eta_l \rangle, U | \zeta_{l'} \rangle, \) and \( U | \eta_{l'} \rangle \) are independent, and therefore that \( | \zeta_l \rangle, | \eta_l \rangle, | \zeta_{l'} \rangle, \) and \( | \eta_{l'} \rangle \) are independent.

Next, a small observation proves a stronger version of \( 2.1 \).

**Lemma 3.3.** Suppose that for some \( 1 \leq l < l' \leq n \) we have \( A_l | \psi \rangle = A_{l'} | \psi \rangle \) and \( C_l | \psi \rangle = C_{l'} | \psi \rangle \). Then \( B_l | \psi \rangle = -B_{l'} | \psi \rangle \), the dimension of \( \langle T_l, T_{l'} \rangle \) is three, and \( \langle T_l, T_{l'} \rangle \) is orthogonal to \( -i | \psi \rangle \) and to \( A_j | \psi \rangle, B_j | \psi \rangle, C_j | \psi \rangle \) for all \( j \not\in \{l, l'\} \).

**Proof.** We only need to prove that \( B_l | \psi \rangle = -B_{l'} | \psi \rangle \). The rest of the statement follows from \( 2.1 \) Equation \( 2.1 \) and the hypothesis \( A_l | \psi \rangle = A_{l'} | \psi \rangle \) imply that \( (-1)^i c_l = (-1)^{i'} c_{l'} \), so if \( c_l \neq 0 \) then \( i_l = i_{l'} \mod 2 \). It follows that if \( c_l \neq 0 \) then \( i_l = i_{l'} + 1 \mod 2 \). Equation \( 2.1 \) and the hypothesis \( C_l | \psi \rangle = C_{l'} | \psi \rangle \) imply that \( c_{l_l} = c_{l_{l'}} \) for all \( I \). Hence, for all \( I \) we have
\[
\langle I | B_l | \psi \rangle = (-1)^i c_l = (-1)^{i_l + 1} c_{l_{l'}} = -\langle I | B_{l'} | \psi \rangle.
\]
This establishes the claim. □

The strengthened Lemma 3.3 yields the following strengthened version of 2.5.

We omit the proof because it requires only a minor change to apply 3.3 in the proof of 2.5.

Proposition 3.4. Strengthened version of 2.5. Let $|\psi\rangle$ be a state vector and let $M$ be its associated matrix. Suppose that $\dim \langle T_l, T_{l'} \rangle \leq 4$ for some $1 \leq l < l' \leq n$. Then $|\psi\rangle$ is local unitary equivalent to a state vector $|\psi'\rangle$ such that $A_l |\psi'\rangle = A_{l'} |\psi'\rangle$, $B_l |\psi'\rangle = -B_{l'} |\psi'\rangle$, $C_l |\psi'\rangle = C_{l'} |\psi'\rangle$, the dimension of $\langle T_l, T_{l'} \rangle$ is three, and $\langle T_l, T_{l'} \rangle$ is orthogonal to $-i |\psi\rangle$ and to $A_j |\psi\rangle$, $B_j |\psi\rangle$, $C_j |\psi\rangle$ for all $j \notin \{l, l'\}$.

Next we state and prove a stronger version of 2.6.

Proposition 3.5. Minimum rank for submatrices of $M$: Let $S = T_{i_1} \cup T_{i_2} \cup \cdots \cup T_{i_q} \cup \{-i|\psi\rangle\}$ be a union of $q$ triples together with the rightmost column $-i|\psi\rangle$ of $M$. Then

$$\dim \langle S \rangle \geq \begin{cases} 
\frac{3q}{2} + 1 & \text{if } q \text{ even} \\
\frac{3q + 1}{2} + 1 & \text{if } q \text{ odd}
\end{cases}$$

Proof. Let $S_0 \subseteq S$ be a union of some number $p$ of triples, maximal with respect to the property that $\langle S_0 \rangle$ contains a subspace $W$ for which

(i) $\dim W \geq \begin{cases} 
\frac{3p}{2} & \text{if } p \text{ even} \\
\frac{3p + 1}{2} & \text{if } p \text{ odd}
\end{cases}$

and

(ii) $W \perp \langle C \setminus S_0 \rangle$.

We separate the argument into cases. We show that in every case, either 3.5 holds or we can derive a contradiction by constructing a superset $S_1$ such that $S_0 \subseteq S_1 \subseteq S$, and $S_1$ is the union of some number $p' > p$ triples and contains a subspace $W'$ satisfying properties (i) and (ii) with $p'$ in place of $p$. The construction of $S_1$ violates the maximality of $S_0$ and therefore rules out the case in question.

Case 1: Suppose that $p = q$. Then 3.5 holds.

Case 2: Suppose that $p < q$ and that the triples $T_{j_1}, T_{j_2}, \ldots, T_{j_{q-p}}$ in $S \setminus S_0$ have the maximum possible span, that is,

$$\dim \langle T_{j_1}, T_{j_2}, \ldots, T_{j_{q-p}} \rangle = 3(q - p).$$

Properties (i) and (ii) imply that

$$\dim \langle S \rangle \geq \dim W + \dim \langle S \setminus S_0 \rangle \geq \frac{3p}{2} + 3(q - p) = \frac{6q - 3p}{2} \geq \frac{6q - (3q - 3)}{2} = \frac{3q + 3}{2} = \frac{3q + 1}{2} + 1$$

(since $p \leq q - 1$)
and so 3.5 holds. Note that if \( p = q - 1 \), the hypothesis of full span is met by 2.2. Therefore in the remaining cases we need only consider \( p \leq q - 2 \).

Case 3: Suppose \( p \leq q - 2 \) and that there is a pair of triples \( T_l, T_{l'} \) in \( S \setminus S_0 \) with \( \dim(T_l, T_{l'}) \leq 4 \). Let \( S_1 = S_0 \cup T_l \cup T_{l'} \), let \( p' = p + 2 \), and let \( W' = W \oplus (T_l \cup T_{l'}) \), where \( \oplus \) denotes the orthogonal direct sum. That the sum is orthogonal is guaranteed by property (ii) for \( W \). Proposition 2.5 implies that property (ii) also holds for the pair \((S_1, W')\) and that \( \dim W' \geq \dim W + 3 \) (in fact, we have equality by 3.4). It follows that if \( p \) is even, so is \( p' \) and we have

\[
\dim W' \geq \frac{3p}{2} + 3 = \frac{3p + 6}{2} = \frac{3(p + 2)}{2} = \frac{3p'}{2}
\]

and similarly if \( p \) and \( p' \) are odd we have

\[
\dim W' \geq \frac{3p + 1}{2} + 3 = \frac{3p' + 1}{2}
\]

so \((S_1, W')\) satisfies property (i). Thus \( S_1 \) violates the maximality of \( S_0 \), so we conclude that the hypothesis of case 3 is impossible.

Case 4: Suppose \( p \leq q - 2 \) and that there is a pair of triples \( T_l, T_{l'} \) in \( S \setminus S_0 \) such that \( \dim(T_l, T_{l'}) = 5 \). Applying 3.2 we have four independent vectors

\[
|\zeta_l\rangle, |\eta_l\rangle \in \langle T_l\rangle, \quad |\zeta_{l'}\rangle, |\eta_{l'}\rangle \in \langle T_{l'}\rangle
\]

orthogonal to all column vectors of \( M \) in columns outside of triples \( T_l, T_{l'} \), so once again \( S_1 = S_0 \cup T_l \cup T_{l'} \) with the subspace

\[
W' = W \oplus \langle |\zeta_l\rangle, |\eta_l\rangle, |\zeta_{l'}\rangle, |\eta_{l'}\rangle \rangle
\]

violates the maximality of \( S_0 \). We conclude that the hypothesis of case 4 is impossible.

Case 5: The only remaining possibility is that \( p \leq q - 3 \). Let \( T = \{T_{j_1}, T_{j_2}, \ldots, T_{j_m}\} \) be a set of triples in \( S \setminus S_0 \) with \( m \geq 3 \) minimal with respect to the property

\[
\dim(T_{j_1}, T_{j_2}, \ldots, T_{j_m}) < 3m.
\]

Applying 2.3 we have 2 vectors

\[
|\zeta_k\rangle, |\eta_k\rangle \in \langle T_k\rangle
\]

for each of the \( m' \geq 2 \) elements \( k \in K \). Let

\[
S_1 = S_0 \cup \left( \bigcup_{k \in K} T_k \right)
\]

let \( p' = p + m' \), and let

\[
W' = W \oplus \langle \{|\zeta_k\rangle, |\eta_k\rangle\}_{k \in K} \rangle.
\]

Note that property (ii) holds for \((S_1, W')\). If \( m' < m \), then the \( 2m' \) vectors in \( \{|\zeta_k\rangle, |\eta_k\rangle\}_{k \in K} \) are independent by the minimality of \( T \), so we have

\[
\dim W' \geq \dim W + 2m' \geq \frac{3p}{2} + 2m' = \frac{3p' + m'}{2} \geq \frac{3p' + 1}{2}
\]
so property (i) holds for \((S_1, W')\), but this contradicts the maximality of \(S_0\). Finally, if \(m' = m\), then \(m \geq 4\) (since \(m'\) is even) and at least \(2(m-1)\) of the vectors in \(\{|\psi_k\rangle, |\eta_k\rangle\}_{k \in K}\) must be independent, again by the minimality of \(T\).

If \(p\) is even, then \(p' = p + m\) is also even and we have
\[
\dim W' \geq \dim W + 2(m-1) \geq \frac{3p}{2} + 2(m-1) = \frac{3p' + m - 4}{2} \geq \frac{3p'}{2}.
\]

If \(p\) is odd, then \(p' = p + m\) is odd and we have
\[
\dim W' \geq \dim W + 2(m-1) \geq \frac{3p + 1}{2} + 2(m-1) = \frac{3p' + m - 3}{2} \geq \frac{3p'}{2} + 1.
\]

Thus \(S_1\) with the subspace \(W'\) violates the maximality of \(S_0\). We conclude that the hypothesis of case 5 is impossible.

Having exhausted all possible cases, this completes the proof of 3.5.

□

Next we state and prove a general statement about additivity of ranks for bipartite states.

**Proposition 3.6.** Let \(|\psi\rangle = |\psi_1\rangle \otimes |\psi_2\rangle\) be a state vector for a bipartite state, where \(|\psi_j\rangle\) is an \(n_j\)-qubit state vector for \(j = 1, 2\). Let \(M\) be the matrix associated to \(|\psi\rangle\), and let \(M_j\) denote the associated matrix for \(|\psi_j\rangle\) for \(j = 1, 2\). Let \(S_1\) and \(S_2\) be the following submatrices of \(M\)
\[
S_1 = T_1 \cup T_2 \cup \cdots \cup T_{n_1} \cup \{-i|\psi\rangle\},
S_2 = T_{n_1+1} \cup T_{n_2+2} \cup \cdots \cup T_{n_1+n_2} \cup \{-i|\psi\rangle\},
\]
and let \(B' = T_{j_1} \cup T_{j_2} \cup \cdots \cup T_{j_m}\) be a union of triples in \(M_1\) with corresponding union \(B = T_{j_1} \cup T_{j_2} \cup \cdots \cup T_{j_m}\) in \(M\). We have
\[
(i) \hspace{1cm} \text{rank}_R M - 1 = (\text{rank}_R M_1 - 1) + (\text{rank}_R M_2 - 1),
(ii) \hspace{1cm} \text{rank}_R M_j = \dim(\langle S_j \rangle) \text{ for } j = 1, 2, \text{ and}
(iii) \hspace{1cm} \dim(B') = \dim(\langle B \rangle).
\]

PROOF. Let \(x\) denote the state represented by \(|\psi\rangle\) and let \(G\) denote the local unitary group. Let \(x_j\) denote the state represented by \(|\psi_j\rangle\), and let \(G_j\) denote the local unitary group for \(j = 1, 2\), so we have \(G = G_1 \times G_2\).

It is easy to see that the \(G\)-orbit of \(x\) is diffeomorphic to the product of the \(G_j\)-orbits of the \(x_j\), so dimensions add.
\[
\dim Gx = \dim G_1 x_1 + \dim G_2 x_2
\]

Applying 2.1 it follows immediately that (i) holds.

For (ii), observe that the columns of \(S_j\) are simply the columns of \(M_j\) tensored with \(|\psi_2\rangle\). The same reasoning applied to the subset \(B \subseteq S_1\) establishes (iii).

□

We end this section with statements about factoring singlets and unentangled qubits.

**Proposition 3.7.** There are two triples \(T_1, T_{i'}\) with \(\dim(T_1, T_{i'}) = 3\) if and only if the state factors as a product of a singlet in qubits \(I, I'\) times a state in the remaining qubits.
Proof. Without loss of generality, let us renumber the qubits so that \( l = 1, l' = 2 \).

First we prove the “if” part of the statement. Let \(|\psi\rangle = |s\rangle \otimes |\phi\rangle\) where \(|s\rangle\) is a singlet in qubits 1 and 2, and \(|\phi\rangle\) is an \((n - 2)\)-qubit state. Then \(|\psi\rangle\) is local unitary equivalent to \(|\psi'\rangle = |s'\rangle \otimes |\phi\rangle\), where \(|s'\rangle = |00\rangle + |11\rangle\). A simple calculation shows that the two triples in the matrix for a 2-qubit singlet state vector \(|s'\rangle\) together span three dimensions. Therefore by \(8.4\) (iii), the dimension of the span of triples 1 and 2 in the matrix for \(|\psi'\rangle\) is also three. Since the rank of unions of triples is local unitary invariant by \(8.1\), we conclude that the dimension of the span of triples 1 and 2 in the matrix for \(|\psi\rangle\) is also three.

Next we prove “only if.” Let \(|\psi\rangle\) be a state vector for which \(\dim(T_1, T_2) = 3\). By \(8.3\) \(|\psi\rangle\) is local unitary equivalent to state vector \(|\psi'\rangle\) for which \(A_1 |\psi'\rangle = A_2 |\psi'\rangle\) and \(C_1 |\psi'\rangle = C_2 |\psi'\rangle\). Equation \(10\) and the hypothesis \(A_1 |\psi\rangle = A_2 |\psi\rangle\) imply that \((-1)^{i_1}c_I = (-1)^{i_2}c_I\), so if \(c_I \neq 0\) then \(i_1 = i_2 \mod 2\), so every \(I\) for which \(c_I \neq 0\) has either both zeros or both ones in the first two indices. Equation \(11\) and the hypothesis \(C_1 |\psi\rangle = C_2 |\psi\rangle\) imply that \(c_{i_1} = c_{i_2}\) for all \(I\). Apply this to \(I\) for which \(i_1 \neq i_2\) and we get

\[
c_{(00i_3i_4...i_n)} = c_{(11i_3i_4...i_n)}
\]

for all \((i_3i_4...i_n)\). It follows that \(|\psi'\rangle\) factors as a product

\[
|\psi'\rangle = (|00\rangle + |11\rangle) \otimes |\phi\rangle
\]

where \(|\phi\rangle\) is an \((n - 2)\)-qubit state. Therefore \(|\psi\rangle\) is a product of a singlet state in the first two qubits times a state in the remaining qubits.

Lemma 3.8. If \(A_j |\psi\rangle = i |\psi\rangle\) then the \(j\)th qubit is entangled.

Proof. Renumber the qubits, if necessary, so that \(j = 1\). By \(11\), the hypothesis \(A_1 |\psi\rangle = i |\psi\rangle\) implies that if \(c_I \neq 0\) then \(i_1 = 0\). Therefore \(|\psi\rangle\) factors as a product

\[
|\psi\rangle = |0\rangle \otimes |\phi\rangle
\]

where \(|\phi\rangle\) is an \((n - 1)\)-qubit state vector.

Proposition 3.9. If the dimension of the span of a triple together with the rightmost column \(-i |\psi\rangle\) is three, then the state factors as an unentangled qubit times a state in the remaining qubits.

Proof. Let \(T_j\) be a triple such that \(\dim(T_j \cup \{-i |\psi\rangle\}) = 3\). Since \(i |\psi\rangle\) lies in the span of \(T_j\), we may write

\[
i |\psi\rangle = \alpha A_j |\psi\rangle + \beta B_j |\psi\rangle + \gamma C_j |\psi\rangle
\]

for some real \(\alpha, \beta, \gamma\). Choose \(R \in \text{SO}(\text{su}(2))\) such that

\[
R(A) = \alpha A + \beta B + \gamma C.
\]

Since the adjoint representation \(\text{Ad} : \text{SU}(2) \rightarrow \text{SO}(\text{su}(2))\) is surjective, we can choose \(U_j \in \text{SU}(2)\) such that \(\text{Ad}(U_j^*) = R\), that is, \(U_j^*XU_j = R(X)\) for all \(X \in \text{su}(2)\). For \(1 \leq k \leq n, k \neq j\), set \(U_k\) equal to the identity. Finally, let \(U \in G = \text{SU}(2)^n\) be \(U = \prod_{i=1}^n U_i\). We have

\[
U^\dagger A_j U |\psi\rangle = i |\psi\rangle.
\]
Applying $U$ to both sides, we obtain

$$A_j U |\psi\rangle = iU |\psi\rangle.$$  

Applying Lemma 3.8 to the matrix $M'$ for the state $U |\psi\rangle$ shows that the $j$th qubit is unentangled for the state $U |\psi\rangle$. Since unentanglement of a particular qubit is local unitary invariant, the proposition is established. □

Proposition 3.10. Rank of unentangled triples: If a state has $k$ unentangled qubits, the rank of the union of the triples corresponding to those qubits together with the rightmost column $-i |\psi\rangle$ of $M$ is $2k + 1$.

Proof. Let $|\psi\rangle$ be a state vector for a state with $k$ unentangled qubits, and let us renumber the qubits, if necessary, so that the unentangled qubits are numbered 1 through $k$. The state vector $|\psi\rangle$ is local unitary equivalent to a state vector $|\psi'\rangle = |00\cdots0\rangle \otimes |\phi\rangle$ where $|00\cdots0\rangle$ is the product of $k$ unentangled qubits and $|\phi\rangle$ is an $(n-k)$-qubit state. Let $M'$ be the matrix associated to $|\psi'\rangle$, $M_1$ the matrix for $|00\cdots0\rangle$, and $M''$ the matrix for the single qubit state $|0\rangle$. Apply 3.6 (i) to $|00\cdots0\rangle = |0\rangle \otimes \cdots \otimes |0\rangle$ to get $\text{rank}_R M_1 = 2k + 1$ (using the fact that the single qubit state $|0\rangle$ has $\text{rank}_R M'' = 3$). Then apply 3.6 (ii) to the set $S_1$ which is the union of the first $k$ triples of the matrix $M'$ together with the column $-i |\psi'\rangle$ to get $\dim(S_1) = \text{rank}_R M_1 = 2k + 1$. Finally, apply 3.1 to conclude that the desired statement holds for $|\psi\rangle$. □

4 Minimum dimension orbit classification

Now we prove that any state with minimum orbit dimension is a product of singlets for $n$ even, times an unentangled qubit for $n$ odd.

Main Lemma 4.1. For $n \geq 2$, if $M$ has minimum rank, then there is some pair of triples whose span is three dimensional.

Proof. Suppose not. A consequence of 3.4 is that every pair of triples spans either three, five or six dimensions. We can rule out the possibility that some pair of triples spans five dimensions, as follows. If there is a pair $T_l, T'_l$ of triples which spans five dimensions, then by 3.2, the pair contributes four independent column vectors which are orthogonal to every column vector in the set $S = \mathcal{C} \setminus (T_l \cup T'_l)$. Applying 3.5 to $S$ with $q = n - 2$, we have

$$\text{rank} M \geq 4 + \begin{cases} \frac{3n^2}{2} + 1 & n \text{ even} \\ \frac{3n^2 - 1}{2} + 1 & n \text{ odd} \end{cases}$$

which is greater than minimum, and therefore impossible.

Thus we need only consider the case where every pair of triples spans six dimensions.

Let $T = \{T_{j_1}, T_{j_2}, \ldots, T_{j_m}\}$ be a set of $m$ triples minimal with respect to the property

$$\dim(T_{j_1}, T_{j_2}, \ldots, T_{j_m}) < 3m$$
Lyons and Walck, Classification of n-qubit states with min. orb. dimension 11

(“minimal” means that \( T \) contains no proper subset of triples which satisfy the given property; thus, any subset of \( m' < m \) triples of \( T \) has “full” span of \( 3m' \) dimensions). We know such a \( T \) exists since the rank of \( M \) is minimum. Apply 2.3 to get a subset \( K \subseteq \{j_1, j_2, \ldots, j_m\} \) with some even positive number \( m' \) of elements and vectors \(|\zeta_k\rangle, |\eta_k\rangle \) in \( T_k \) for \( k \in K \). Let \( T' = \bigcup_{k \in K} T_k \) and let \( S = C \setminus T' \) be the union of the \( q = n - m' \) triples not in \( T' \) together with the rightmost column \( -i|\psi\rangle \) of \( M \).

If \( m' < m \), the minimality of \( T \) guarantees that the \( 2m' \) vectors \( \{ |\zeta_k\rangle, |\eta_k\rangle \}_{k \in K} \) are independent, so the rank of \( M \) is at least (apply 2.3 to \( S \) with \( q = n - m' \))

\[
\text{rank}(M) \geq 2m' + \begin{cases} 
\frac{3q+1}{2} + 1 & n \text{ even} \\
\frac{3q+1}{2} + 1 & n \text{ odd}
\end{cases}
\]

which is greater than minimum, so this case cannot occur.

If \( m' = m \), the minimality of \( T \) guarantees that at least \( 2(m' - 1) \) of the vectors in \( \{ |\zeta_k\rangle, |\eta_k\rangle \}_{k \in K} \) are independent, so the rank of \( M \) is at least

\[
\text{rank}(M) \geq 2(m' - 1) + \begin{cases} 
\frac{3q+1}{2} + 1 & n \text{ even} \\
\frac{3q+1}{2} + 1 & n \text{ odd}
\end{cases}
\]

which is greater than minimum, so this case cannot occur.

If \( m' > 4 \), this is greater than minimum, so we may assume that \( m' = m \leq 4 \).

We rule out the possibility \( m = 2 \) since every pair of triples spans six dimensions, so the only remaining case is \( m' = m = 4 \). We may further assume that every minimal set of triples that has less than full span consists of \( m = 4 \) triples, and that applying 2.3 to such a set yields \( m' = 4 \). Thus the columns of \( M \) decompose into a disjoint union

\[
C = S_0 \cup T_1 \cup T_2 \cup \cdots \cup T_t
\]

where each \( T_i \) is a union of four triples for which applying 2.3 yields six independent vectors orthogonal to \( \langle C \setminus T_i \rangle \), and \( S_0 \) is a union of \( q = n - 4t \) triples together with the rightmost column \( -i|\psi\rangle \) of \( M \) such that the span of the union of the triples in \( S_0 \) is \( 3q \) dimensional.

We consider the cases \( q \geq 2 \), \( q = 0 \), and finally \( q = 1 \).

If \( q \geq 2 \) then we have

\[
\text{rank}(M) \geq 6t + 3q = 6 \left( \frac{n-q}{4} \right) + 3q = \frac{3n+3q}{2}
\]

which is greater than minimum, so this case cannot occur.

If \( q = 0 \) or \( q = 1 \), let \( S_1 = S_0 \cup T_1 \) and consider the disjoint union

\[
C = S_1 \cup T_2 \cup \cdots \cup T_t
\]

of the set \( S_1 \) with \( t' = t - 1 \) unions of four triples \( \{T_i\}_{i=2}^{t} \).
If \( q = 0 \), \( S_1 \) has a span of at least nine dimensions since any three of the triples in \( T_1 \) have full span. We have

\[
\text{rank} M \geq 9 + 6t = 9 + 6 \left( \frac{n - 4}{4} \right) = \frac{3n + 6}{2}
\]

which is greater than minimum, so this case cannot occur.

If \( q = 1 \), then \( S_1 \) is the union of five triples together with the rightmost column \(-i |\psi\rangle\). If any subset of four of those five triples has full span, then we have

\[
\text{rank} M \geq 12 + 6t = 12 + 6 \left( \frac{n - 5}{4} \right) = \frac{3n + 9}{2}
\]

which is greater than minimum, so it must be the case that all subsets of four triples have less than full span, so any subset of four triples contributes six independent vectors orthogonal to the remaining triple and the rightmost column \(-i |\psi\rangle\) of \( M \). If any one of the qubits corresponding to one of the five triples is not unentangled, then by \( 3.9 \) we have

\[
\text{rank} M \geq 6 + 4 + 6t = 10 + 6 \left( \frac{n - 5}{4} \right) = \frac{3n + 5}{2}
\]

which is greater than minimum, so it must be the case that all five qubits are unentangled. But then by \( 3.10 \) we have

\[
\text{rank} M \geq 11 + 6t = 11 + 6 \left( \frac{n - 5}{4} \right) = \frac{3n + 7}{2}
\]

which is greater than minimum.

Since all possible cases lead to contradictions, we conclude that some pair of triples must have a three dimensional span.

**Corollary 4.2.** Any state which has minimum orbit dimension is a product of singlets when \( n \) is even, together with an unentangled qubit when \( n \) is odd.

**Proof.** Let \( |\psi\rangle \) be a state vector for a state with minimum orbit dimension, with associated matrix \( M \). Apply Lemma 4.1 to \( M \) to get a pair of triples whose span is three dimensional. By \( 5.4 \), \( |\psi\rangle \) factors as a product of a singlet in those two qubits times an \((n - 2)\)-qubit state, say, with state vector \( |\psi_1\rangle \), in the remaining qubits. Let \( M_1 \) be the matrix associated to \( |\psi_1\rangle \). By \( 5.6 \)(i), \( M_1 \) also has minimum rank. Repeating this reasoning yields a sequence \( |\psi\rangle, |\psi_1\rangle, |\psi_2\rangle, \ldots \) which eventually exhausts all the qubits of \( |\psi\rangle \) unless \( n \) is odd, in which case a single unentangled qubit remains.

Next we classify states with minimum orbit dimension up to local unitary equivalence.

**Proposition 4.3.** Separation of singlet products: Products of singlets are local unitary equivalent if and only if the choices of entangled pairs are the same in each product.

**Proof.** If \( |\psi\rangle \) is a product of singlets for which some pair of qubits, say qubits 1 and 2, forms a singlet, then \( |\psi\rangle \) is of the form \( |\alpha\rangle \otimes |\beta\rangle \), where \( |\alpha\rangle \) is a singlet in qubits 1 and 2. Clearly, any state local unitary equivalent to \( |\psi\rangle \) is also of this form.

The following classification theorem summarizes the results of this section.
Theorem 4.4. Classification of states with minimum orbit dimension: An $n$-qubit pure state has minimum orbit dimension $3n/2$ ($n$ even) or $(3n + 1)/2$ ($n$ odd) if and only if it is a product of singlets, together with an unentangled qubit for $n$ odd. Furthermore, two of these states which do not have the same choices for pairs of entangled qubits are not local unitary equivalent.

5 Conclusion

The classification of types of quantum entanglement is a difficult but central problem in the field of quantum information. Entanglement types partially distinguish themselves by their local unitary orbit and their orbit dimension. As an integer that can be readily calculated for a given quantum state, orbit dimension is a convenient LU invariant. It provides a useful “first stratification” of quantum state space, which suggests a two-step program for entanglement classification. The first step is to understand the possible orbit dimensions for a composite quantum system, and the second step is to understand the types of entanglement that occur in each orbit dimension. For pure states of $n$-qubits, the first step was achieved in [8]. The present work completes the second step for the orbits of minimum dimension. In particular, states with minimum orbit dimension are precisely products of pairs of qubits, each pair in a singlet state (or LU equivalent). While there is much work left to be done in the second step of the classification program, it is worth remarking that the present results, dealing with an arbitrary number of qubits, give some hope that a meaningful classification of entanglement for $n$ qubits is possible.

Reduced orbit dimension states appear to be the most interesting states. Carteret and Sudbery [7] pointed out that reduced orbit dimension states (which they call “exceptional states”) must have extreme values of the local unitary invariants that are used in the construction of all measures of entanglement. They concluded that reduced orbit dimension states should be expected to be particularly interesting and important. Subsequent studies have confirmed this expectation. All of the “famous” states that theorists use for examples and that experimentalists try to exhibit in the laboratory have reduced orbit dimension (examples include the EPR singlet state, the GHZ state, unentangled states, the W state, and $n$-cat states). Both the most entangled and the least entangled states states have reduced orbit dimension.

Orbit dimension provides a useful first step in entanglement classification, but the numerical value of orbit dimension, beyond providing a sense of how rare an entanglement type is, does not carry a simple physical meaning. For example, in the case of pure three-qubit states [8, 9], the minimum orbit dimension is 5 and the maximum orbit dimension is 9. States with orbit dimension 5 consist only of products of a singlet pair and a qubit, orbit dimension 6 contains the unentangled states, orbit dimension 7 contains GHZ states as well as products of generic two-qubit states with an unentangled qubit, orbit dimension 8 contains the W state, and orbit dimension 9 contains all generic states.

Minimum orbit dimension states have the most symmetry with respect to local transformations in that they remain invariant under a larger class of transformations than any other states. They are maximal symmetry generalizations of the spin singlet state, which is invariant (as a quantum state, not an entanglement type) to any rotation applied identically to both spins. The present result, that
the $n$-qubit maximal symmetry generalizations of the two-qubit singlet state are themselves products of singlets, shows a special role for the two-qubit singlet state in the theory of $n$-qubit quantum entanglement.

Linden, Popescu, and Wootters [10, 11] have shown that almost all pure $n$-qubit quantum states lack essential $n$-qubit quantum entanglement in the sense that they can be reconstructed from their reduced density matrices. It appears likely (and is known in the three-qubit case) that states with essential $n$-qubit entanglement are found among the reduced orbit dimension states. The present work shows that minimum orbit dimension states do not exhibit essential $n$-qubit entanglement for $n \geq 3$. Rather, minimum orbit dimension states maximize pairwise entanglement. We conjecture that states with minimum orbit dimension among non-product states have essential $n$-qubit entanglement in the sense of [10, 11].
