COMPLEX ZEROS OF THE JONQUIÈRE OR POLYLOGARITHM FUNCTION

B. Fornberg and K.S. Kölbig

Abstract

Complex zero trajectories of the function

$$F(x,s) = \sum_{k=1}^{\infty} x^k/k^s$$

are investigated for real $|x| < 1$ in the complex s -plane. It becomes apparent that there exist several classes of such trajectories, depending on their behaviour for $|x| \rightarrow 1$. In particular, trajectories are found which tend towards the zeros of the Riemann zeta function $\zeta(s)$ as $x \rightarrow -1$, and approach these zeros closely as $x \rightarrow 1 - \rho$ for small but finite $\rho > 0$. However, the latter trajectories appear to descend to the point $s = 1$ as $\rho \rightarrow 0$. Both for $x \rightarrow -1$ and $x \rightarrow 1$, there are trajectories which do not tend towards zeros of $\zeta(s)$. The asymptotic behaviour of the trajectories for $|x| \rightarrow 0$ is discussed. A conjecture of Pickard concerning the zeros of $F(x,s)$ is shown to be false.

AMS 1970 subject classification. Primary 33A70; Secondary 10H05.

Key words and phrases. Jonquière function, polylogarithms, Lerch's transcendent, Riemann zeta function, Dirichlet series, complex zeros.

1. INTRODUCTION

Let $s = \sigma + it$ and $z = x + iy$ be two complex variables. The Jonquière function can then be defined by the infinite sum [1] [2]

$$F(z, s) = \sum_{k=1}^{\infty} \frac{z^k}{k^s} \quad (|z| < 1) \quad (1)$$

or by the definite integral

$$F(z, s) = \frac{z}{\Gamma(s)} \int_0^{\infty} \frac{\xi^{s-1}}{e^{\xi} - z} d\xi \quad (2)$$

$$(\sigma > 0, -\pi < \arg(1 - z) < \pi; \quad \sigma > 1, z = 1)$$

This function is a special case of the Lerch transcendent

$$\Phi(z, s, \alpha) = \sum_{k=0}^{\infty} \frac{z^k}{(\alpha + k)^s} \quad (3)$$

namely $F(z, s) = z\Phi(z, s, 1)$.

These functions have been investigated by several authors, and theoretical results as well as references can be found in the relevant handbooks [1] [2]. For certain special values of the parameters, these functions and some generalizations appear in several fields of mathematics and applications, occasionally under different names. For instance, if $s = n$ is a positive integer, one has the so-called polylogarithms (n -logarithms, or Spence functions):

$$S_n(z) \equiv L_n(z) \equiv Li_n(z) = \sum_{k=1}^{\infty} \frac{z^k}{k^n}. \quad (4)$$

These functions, in particular for small values of n , have been investigated by several authors (for references, see Lewin [3]). They have been generalized in an important way in a little-known paper by Nielsen [4] at the beginning of this century. During the last few years, interest in the polylogarithms and the Nielsen functions $S_{np}(z)$ has revived in two connections. On the one hand there is the study of the functional relations which they satisfy, especially in relation to other fields of mathematics like group theory and geometry, e.g. Wechsung [5] and in the book of Maier and Kiesewetter [6] for the polylogarithms. On the other hand there is the importance of these functions in the theory of Feynman integrals

in quantum electrodynamics, since they allow closed expressions to be obtained for certain n-dimensional integrals over rational functions. These integrations are very involved, but can be handled to a large extent by algebraic manipulation on a computer (see, for example, Maison and Petermann [7]). Problems relating the integration of rational functions and the polylogarithms are also treated by Wechsung [8]. A method for the numerical evaluation of a few Nielsen functions (and polylogarithms) for real x using Chebyshev expansions can be found in [9], and a method for computing $S_2(z)$ and $S_3(z)$ for complex argument with the help of continued fraction expansions is given by Jacobs and Lambert [10]. Although most of the applications seem to be restricted to integers $s = n$, Truesdell [11] investigated $F(z,s)$ because this function with $s = -1/2, 1/2, 3/2$ occurs in the theory of the structure of polymers.

Our interest in the function $F(z,s)$ lies in another direction. Since for $z = 1$, $F(z,s)$ is identical with the Riemann zeta function

$$F(1,s) = \zeta(s) = \sum_{k=1}^{\infty} \frac{1}{k^s} \quad (\sigma > 1) \quad (5)$$

it would be interesting to know how the zeros of $F(z,s)$, if there are any, approach the zeros of $\zeta(s)$ on the line $\sigma = 1/2$ as $z \rightarrow 1$, if in fact they do. The problem of the zeros of $F(z,s)$ has been raised by Pickard [12], who, a few years ago, investigated the function $F(z,s)$ for complex z and s , noting that but little information about these zeros is available. He stated that "as $z \rightarrow 0$, the zeros are given by

$$s = \frac{1}{\log 2} [\log |z| + i \arg z + (2p - 1)\pi i] \quad (6)$$

and was "tempted to conjecture that all zeros in the complex (z,s) -plane lie on trajectories that lead to the line

$$\sigma = \frac{\log |z|}{\log 2} \quad (7)$$

as $z \rightarrow 0$ and the line $\sigma = 1/2$ as $z \rightarrow 1$ ".

It is the aim of this paper to show, by theoretical considerations and numerical calculation that both the statement (6) and the conjecture (7) are erroneous. In fact, Pickard has revealed only a very small corner of the amazing and fascinating picture constituted by the zeros of $F(z,s)$.

In order to make the approach to the problem simpler, we restrict ourselves to real values of z , namely $-1 < x < 1$, $y = 0$, and leave the general case for

possible further research. We therefore search for trajectories of $F(x,s) = 0$ in the complex s -plane, where x is a parameter along these trajectories. Further, it is sufficient to consider only the upper half plane $t > 0$.

2. ASYMPTOTES FOR THE ZEROS OF $F(x,s)$

In order to investigate the behaviour of the zeros of $F(x,s)$ for $x \rightarrow +0$, we rewrite equation (1) as

$$\begin{aligned} G_N(x,s) &= \frac{N^s}{x} F(x,s) \\ &= \frac{(N/1)^s}{x^{N-1}} + \frac{(N/2)^s}{x^{N-2}} + \dots + 1 + \frac{x}{[(N+1)/N]^s} + \\ &\quad + \frac{x^2}{[(N+2)/N]^s} + \dots = H_N(x,s) + R_N(x,s), \end{aligned} \quad (8)$$

where

$$\begin{aligned} H_N(x,s) &= 1 + \frac{x}{[(N+1)/N]^s} \\ &= 1 - \exp \left\{ -\log \left(1 + \frac{1}{N} \right) \left[s - \frac{1}{\log \left(1 + \frac{1}{N} \right)} [\log x + (2P + 1)\pi i] \right] \right\} \\ &\quad (P = 0, \pm 1, \pm 2, \dots). \end{aligned} \quad (9)$$

$G_N(x,s)$ has the same zeros as $F(x,s)$, apart from $x = 0$. It is easily seen that the zeros of $H_N(x,s)$ are given for $t > 0$ by

$$\begin{aligned} \hat{s}_0^+(x,P,N) &= \frac{1}{\log \left(1 + \frac{1}{N} \right)} [\log x + (2P + 1)\pi i] \\ &= u^+(x,N) + i v^+(P,N) \end{aligned} \quad (10)$$

$$(N = 1, 2, 3, \dots; P = 0, 1, 2, \dots).$$

We note here that the formula (6) of Pickard corresponds to $N = 1$, and is therefore a special case of this formula.

Our aim is now to show that, if $x \rightarrow +0$, the quantity $\hat{s}_0^+(x,P,N)$ is an asymptotic solution of $F(x,s) = 0$. For this purpose, we note first that the absolute value of term k in $G_N(x,s)$ for $s = \hat{s}_0^+(x,P,N)$ is given by

$$|\text{term } k| = x^{k-N} (N/k) u^+(x,N) = x^{f(k,N)}, \quad (11)$$

where

$$f(k, N) = k - N - \frac{\log(k/N)}{\log\left(1 + \frac{1}{N}\right)}. \quad (12)$$

For fixed N , and as a function of k , it is easy to show that $f(k, N)$ has the following properties:

$$\begin{aligned} f(N, N) &= f(N+1, N) = 0 \\ f(N-1, N) &> f(N+2, N) \end{aligned} \quad (13)$$

$$\frac{d^2}{dk^2} f(k, N) > 0.$$

Therefore, it follows that

$$f(k, N) \geq \epsilon_N > 0 \quad (k \neq N, k \neq N+1) \quad (14)$$

with

$$\epsilon_N = f(N+2, N) = 2 - \frac{\log\left(1 + \frac{2}{N}\right)}{\log\left(1 + \frac{1}{N}\right)}. \quad (15)$$

In addition, $f(k, N) = O(k)$ for $k \rightarrow \infty$. This leads to the conclusion that

$$|R_N(x, s)| = O(x^{\epsilon_N}) \quad (16)$$

for $s = \hat{s}_0^+(x, P, N)$ and $x \rightarrow +0$, independent of $\text{Im } \hat{s}_0^+ = v^+(P, N)$. In order to bound $|R_N(x, s)|$ from above uniformly in a strip around the line $\sigma = u^+(x, N)$ extending to, say, unit distance on either side of the line, we can proceed as follows. Since

$$|\text{term } k| = x^{k-N} \left(\frac{N}{k}\right)^\sigma,$$

a change of up to ± 1 in the value of σ can multiply the magnitude of the term by at most N/k or k/N , whichever is the larger. This does not affect the uniform convergence $O(x^{\epsilon_N})$ as $x \rightarrow 0$ of the sum $|R_N(x, s)|$ in the infinite strip. We now make use of the following lemmas:

Lemma 1. Given any ϵ , $0 < \epsilon < 2\pi$, there exists an $\eta > 0$ such that $|e^s - 1| \geq \eta$ for all complex s on the circle $|s| = \epsilon$. In particular, we can choose η such that $\lim_{\epsilon \rightarrow 0} (\eta/\epsilon) = 1$.

Lemma 2. (Rouché) If f and g are regular analytic functions in a simply connected and bounded region G , and if $f \neq 0$ and $|f| > |g|$ on a closed path Γ completely inside G , then f and $f + g$ have the same number of zeros inside Γ .

We choose a small $\varepsilon > 0$, where $\varepsilon < \log [1 + (1/N)]$. According to Lemma 1 there exists an η such that $|H_N(x, s)| \geq \eta$ if s satisfies

$$\log \left(1 + \frac{1}{N} \right) \left| s - \frac{1}{\log \left(1 + \frac{1}{N} \right)} [\log x + (2P + 1)\pi i] \right| = \varepsilon .$$

If x now is chosen so small that $|R_N(x, s)| < \eta$ in the strip, then according to Lemma 2, $G_N(x, s) = H_N(x, s) + R_N(x, s)$ and thus $F(x, s)$ has one zero at most at the distance $\varepsilon / \log [1 + (1/N)]$ from $\hat{s}_0^+(x, P, N)$. Since we could choose ε arbitrarily small, this proves the existence of asymptotes for the zeros when $x \rightarrow +0$. To each $N = 1, 2, 3, \dots$ and each $P = 0, 1, 2, \dots$ there corresponds one zero given by equation (10).

Using $\eta = \varepsilon + O(1)$ we find that the distance of the zero of $F(x, s)$ to $\hat{s}_0^+(x, P, N)$ is of the type $\text{const} \cdot x^{\varepsilon/N}$, where the constant depends on N but not on x .

From equation (10), we see that the lines

$$t = v^+(P, N) = \frac{(2P + 1)\pi}{\log \left(1 + \frac{1}{N} \right)} \quad (17)$$

which are parallel to the real axis $t = 0$, are asymptotes for the zeros $s_0^+(x, P, N)$ of $F(x, s)$ in the case $x \rightarrow +0$. By considerations similar to those given above, one can find that in the case $x \rightarrow -0$ the zeros of the corresponding function

$$H_N(x, s) = 1 - \frac{|x|}{[(N+1)/N]^s} \quad (18)$$

in the upper half plane $t > 0$ are given by the expression

$$\hat{s}_0^-(x, P, N) = \frac{1}{\log \left(1 + \frac{1}{N} \right)} (\log |x| + 2P\pi i) , , \quad (19)$$

($N = 1, 2, 3, \dots$; $P = 1, 2, 3, \dots$)

and that the asymptotes of the zeros $s_0^-(x, P, N)$ of $F(x, s)$ for $-1 < x < -0$ are characterized by

$$t = v^-(P, N) = \frac{2P\pi}{\log \left(1 + \frac{1}{N} \right)} . \quad (20)$$

3. NUMERICAL COMPUTATION OF THE ZERO TRAJECTORIES OF $F(x,s)$

The numerical computation of the zeros of $F(x,s)$ was made in double precision mode (about 28 digits) on a CDC 7600 computer. It was found that straightforward use of the defining sum (1) was convenient for most of the cases. The summation was carried until the modulus of a term became smaller than 10^{-30} . We started the computation at a parameter value $x = x'$ for given values of P and N and took the value $\hat{s}_0(x', P, N)$ as an approximation to the zero $s_0(x', P, N)$ of $F(x,s)$. This value was then refined with a Newton method [13] to at least five decimals and the value thus obtained was taken as an approximation for $s_0(x' + \Delta x, P, N)$, and so on. It was found that the choice

$$x' = 10^{-N-2}; \quad \Delta x = \min(10^{\lfloor \lg x - x - 1 \rfloor}, 0.01) \quad (21)$$

where $\lfloor \xi \rfloor$ is the integer part of ξ , led in most cases to an efficient and stable computation along the trajectories, giving in addition convenient values for x . In regions where the behaviour of the trajectories was found to be complicated, much smaller values of Δx have been used. For $N \geq 9$, it became more and more difficult to start with $x' = 10^{-N-2}$, and the trajectories were calculated backwards starting near a zero of $\zeta(s)$. With these methods, the trajectories were computed without great difficulties up to $|x| = 0.96$. In the imaginary direction of the s -plane, we restricted the calculation arbitrarily to $0 < t \leq 110$.

4. THE RESULTS

We first describe the results for the case $+0 < x < 1$. Here we found two distinct classes of trajectories, characterized by their behaviour for $x \rightarrow 1$. One class does not approach the zeros of $\zeta(s)$ on the line $\sigma = 1/2$, but tends directly towards the point $s = 1$. We computed seven of these trajectories and found that they belong to asymptotes having $P = 0$, $N = 1, 2, \dots, 7$. They are shown in Fig. 1, giving a very regular picture. Although it is advisable to be very careful in formulating conjectures in the matter treated here, we believe that this class is characterized by $P = 0$, and that all the curves $s_0^+(x, 0, N)$ will be found to belong to it. It is, however, probable that the regular picture will be destroyed when these trajectories pass, for large N , near a zero of $\zeta(s)$.

The other class is characterized by the fact that all the computed trajectories approach very closely a zero of $\zeta(s)$ on the line $\sigma = 1/2$ as $x \rightarrow 1 - \rho$ for small values of $\rho > 0$. These curves are shown in Fig. 2, plotted as full (unbroken) lines. (The behaviour of the trajectories for $\rho \rightarrow 0$ is discussed in Section 5.) The zeros s_m of $\zeta(s)$ are taken from Haselgrove and Miller [14]. The picture presented by this class is complicated, and becomes more and more involved for increasing imaginary part t . Nevertheless, some of the curiosities are especially

worth mentioning. One notices immediately the tongs-like shape of those trajectories which approach zeros of $\zeta(s)$ which are not very far from each other (for example, s_4 and s_5 , s_7 and s_8 , s_9 and s_{10} , s_{13} and s_{14} , etc.). Further, one finds, at least in the lower part of the region considered, a curious "paired" behaviour of trajectories having P and N interchanged, e.g. the pairs $s_0^+(x,1,3)$ and $s_0^+(x,3,1)$, $s_0^+(x,1,7)$ and $s_0^+(x,7,1)$, etc., in particular, $s_0^+(x,2,5)$ and $s_0^+(x,5,2)$, $s_0^+(x,1,9)$ and $s_0^+(x,9,1)$, but also, in a different way, $s_0^+(x,2,3)$ and $s_0^+(x,3,2)$. The asymptotes of these curves are often quite distant from each other, but eventually (outside the picture) these curves separate and approach their asymptotes for $x \rightarrow +0$. Figure 3 shows such a behaviour for $s_0^+(x,1,8)$ and $s_0^+(x,8,1)$. On the other hand, trajectories with $P = N$ are isolated, like $s_0^+(x,1,1)$, $s_0^+(x,2,2)$, $s_0^+(x,3,3)$. Since there can be no interchange of P and N when $P = 0$, the exceptional behaviour of the trajectories $s_0^+(x,0,N)$, as described above, seems more plausible.

For large P and N , we see from (17) that

$$v^+(P,N) \sim \frac{1}{2} (2N + 1)(2P + 1) \pi \sim v^+(N,P) ,$$

which means that two asymptotes with P and N interchanged become quite close to each other. However, this does not necessarily mean that the corresponding trajectories have a similar behaviour as they advance through the s -plane or that they approach neighboured zeros s_m . For instance, $v^+(3,4) = 98.55$ and $v^+(4,3) = 98.28$ differ by 0.27 only, whereas the zeros $s_{26} = 92.49$ and $s_{31} = 103.73$, which are approached by $s_0^+(x,4,3)$ and $s_0^+(x,3,4)$, respectively, have a much larger distance from each other.

Looking at the trajectories which pass near zeros of $\zeta(s)$ which are not far from each other, one notices a certain "indecisive" behaviour of some of these curves, as if the zeros of $\zeta(s)$ are trying to "attract" the trajectories. This can lead to very sharp bends, as for instance for $s_0^+(x,3,1)$. Figure 4 shows a close-up of this curve near the bend.

It is obvious that the behaviour of the trajectories becomes more and more complicated the higher one goes in the s -plane. In particular, there seems to be no way of predicting from P and N the ordinal number m of the zero s_m of $\zeta(s)$ which is approached by the trajectory $s_0^+(x,P,N)$, even if there is a one-to-one correspondence between zeros s_m and trajectories coming from asymptotes $v^+(P,N)$ which is, of course, an open question. Up to s_{33} , however, all zeros of $\zeta(s)$ are approached by exactly one trajectory $s_0^+(x,P,N)$, and we have computed all trajectories belonging to the asymptotes $v^+(P,N) \leq 110$.

For the case $-0 > x > -1$, the trajectories are the broken curves in Fig. 2. Since

$$(1 - 2^{1-s}) \zeta(s) = \sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k^s} \quad (\sigma > 0) \quad (22)$$

one might expect that as $x \rightarrow -1$ some of these trajectories would terminate at the equidistant points

$$s'_m = 1 + \frac{2\pi m}{\log 2} i \approx 1 + 9.06472 mi \quad (m = 1, 2, \dots) \quad (23)$$

which are the zeros of $\phi(s) = 1 - 2^{1-s}$. This is indeed the case. On the other hand, there are also trajectories which approach the zeros of $\zeta(s)$. Therefore, here again we have two classes of trajectories.

It is remarkable that, of all the computed trajectories $s_0^-(x, P, N)$, only those with $N = 1$ tend to a zero s'_m . In fact, the trajectories $s_0^-(x, P, 1)$, $P = 1, 2, \dots, 12$, approach the corresponding s'_P . In addition, we see that

$$\text{Im } s'_P = v^-(P, 1) = \frac{2P\pi}{\log 2} \quad (24)$$

which means that the asymptotes $v^-(P, 1)$ have, for all P , the same ordinate t as the zeros of $\phi(s)$. Therefore, again with the necessary caution, we conjecture that all trajectories $s_0^-(x, P, 1)$ will approach the corresponding zeros s'_P . The remaining trajectories corresponding to $-1 < x < -0$ approach zeros of $\zeta(s)$, often in a smoother way than in the case $+0 < x < 1$. For P and N interchanged, there is no behaviour similar to the $s_0^+(x, P, N)$, although "pairs" and "tongs" are also present. A very interesting case is $s_0^-(x, 2, 8)$, which, after having directed itself towards s_{33} , bends with a sharp loop to s_{32} . A close-up view is shown in Fig. 5. As for the case $+0 < x < 1$, all the zeros of $\zeta(s)$ up to s_{33} are approached by exactly one trajectory $s_0^-(x, P, N)$. One should note that the trajectory $s_0^-(x, 1, 18)$ has its asymptote $v^-(1, 18) = 116.21$ outside the figure and that the trajectory $s_0^-(x, 7, 2)$, coming from $v^-(7, 2) = 108.47$, approaches an s'_m with $t > 110$ outside the figure.

In order to test our calculations, we have applied the well-known theorem

$$Z(x) = \frac{1}{2\pi i} \int_C \frac{F'(x, s)}{F(x, s)} ds \quad (25)$$

giving the number $Z(x)$ of zeros of $F(x, s)$ inside a closed contour C . The integral was evaluated by numerical integration with an adaptive Gaussian quadrature procedure [15]. We found $Z(0.1) = 27$ in the rectangle $(0, 110i, -11 + 110i, -11)$

and $Z(-0.1) = 26$ in the rectangle $(i, 109i, -11 + 109i, -11 + i)$. These values agree with the numbers of computed zeros found in these rectangles (see Fig. 2).

5. TRAJECTORIES FOR x VERY CLOSE TO ONE

In this section we present some heuristic arguments concerning the behaviour of the trajectories $s_0^+(x, P, N)$ as $x \rightarrow 1$.

We shall use the formula [1]

$$F(x, s) = \Gamma(1 - s)(-\log x)^{s-1} + \zeta(s) + \sum_{n=1}^{\infty} \zeta(s - n) \frac{\log^n x}{n!} \quad (26)$$

to study the behaviour of the zeros of $F(x, s)$ as $x \rightarrow 1$, especially those which, for $x \rightarrow 1 - \rho$, initially approach the non-trivial zeros of $\zeta(s)$. As an example, we take the behaviour of $F(x, s)$ near s_1 . When $x \rightarrow 1$, the sum in (26) becomes negligible as compared to $\zeta(s)$, and the zeros of $F(x, s)$ therefore arise effectively from the cancellation between $\zeta(s)$ and the term

$$\Psi(x, s) = \Gamma(1 - s)(-\log x)^{s-1} = \Gamma(1 - s) e^{(s-1)\log(-\log x)}. \quad (27)$$

Since $|\Gamma(1 - s)|$, in the neighbourhood of the first non-trivial zero $s_1 = 1/2 + 14.134725i$ is of the order 10^{-10} (and decreases strongly for an increasing imaginary part of s), $\Psi(x, s)$ is also small near s_1 for x less than, say, $1 - 10^{-8}$. This term has therefore essentially no effect on the zero of $F(x, s)$ in the neighbourhood of s_1 . When x is even closer to one, $\log(-\log x)$ decreases to $-\infty$. Near s_1 the function $\Psi(x, s)$ increases exponentially from a very small value; and the phase rotates with an angle proportional to $\log(-\log x)$. The zero [i.e. the point where this term cancels $\zeta(s)$, which has a simple zero at s_1] therefore starts to rotate in an exponential spiral around s_1 .

To see what happens when x approaches one even more closely, we divide (26) by $\Gamma(1 - s)$. Again ignoring the sum in (26), we study the points where $-\zeta(s)/\Gamma(1 - s)$ is equal to $e^{(s-1)\log(-\log x)}$. For $x \rightarrow 1$, $|e^{(s-1)\log(-\log x)}|$ tends to infinity at every point s for which $\operatorname{Re} s < 1$ and tends to zero for those having $\operatorname{Re} s > 1$. The curve along which $-\zeta(s)/\Gamma(1 - s)$ (which is a regular function for $s = 1$) and $e^{(s-1)\log(-\log x)}$ agree in magnitude thus approaches the line $\operatorname{Re} s = 1$. [Although $-\zeta(s)/\Gamma(1 - s)$ is zero for $s = 2, 3, 4, \dots$, $F(x, s)$ has no zeros in the neighbourhood of these points. The poles of $\Gamma(1 - s)$ are cancelled by the poles of $\zeta(s - n)$ in the sum on the right hand side of (26).] Along this curve, tending to $\operatorname{Re} s = 1$, the phase of $-\zeta(s)/\Gamma(1 - s)$ varies slowly relative to the phase of $e^{(s-1)\log(-\log x)}$, and $F(x, s)$ has zeros when the phase of $-\zeta(s)/\Gamma(1 - s)$ agrees with the phase of $e^{(s-1)\log(-\log x)}$. This occurs at almost equidistant

points [asymptotically spaced at distance $2\pi/|\log(-\log x)|$], all tending to $\text{Im } s = 0$, and thus tending to $s = 1$ when $x \rightarrow 1$.

The explanations given in the above paragraph for the behaviour near $s = 1$ are also valid for those trajectories which tend directly to $s = 1$.

Near $s = 1$, the zero trajectories $s_0^+(x, 0, N)$ were computed in the following way. The method described in Section 3 was used up to $x = 0.98$. For $0.98 < x \leq 1 - 10^{-10}$, the functional equation

$$F(x, s) = 2^{1-s} F(x^2, s) - F(-x, s) \quad (28)$$

was applied. The series $F(-x, s)$ can be summed by means of the Euler transformation [16]. Convergence is then achieved essentially from the fact that $1/k^s$ behaves smoothly as a function of k and not so much from the additional factors x^k . The problem of calculating $F(x, s)$ for x close to one is thus reduced to the calculation of $F(x^2, s)$, i.e. the same problem with a smaller argument x . This recursion was used until the value of x by successive squarings had decreased below 0.5, when a direct summation was done. For example, in the case of $x = 1 - 10^{-10}$, this required 33 steps in the recursion.

For the first trajectory $N = P = 1$, we have investigated numerically the behaviour near the point s_1 , setting $x = 1 - 10^{-\alpha}$. Up to $\alpha = 10$, the recursion method (28) was used and for $\alpha > 10$ formula (26) was used, ignoring the sum term. Figure 6 shows how the trajectory $s_0^+(x, 1, 1)$ initially approaches s_1 and later leaves it in the way described above. The figure also shows three other zero trajectories which pass close to s_1 and join $s_0^+(x, 1, 1)$ on its way to $s = 1$. The small rectangle at the centre of the spiral in Fig. 6 encloses the region which is shown on an enlarged scale in Fig. 7.

For $x \rightarrow -1$, in view of the convergence of the series (1) for $\text{Re } s = \sigma > 0$ and $x = -1$, we believe that the trajectories $s_0^-(x, P, N)$ actually converge to s_m or s'_m .

6. TRAJECTORIES CORRESPONDING TO THE TRIVIAL ZEROS OF $\zeta(s)$

The function $\zeta(s)$ has, apart from the zeros in the strip $0 < \sigma < 1$, so-called trivial zeros at the points

$$s_m'' = -2m \quad (m = 1, 2, 3, \dots) \quad (29)$$

These zeros are approached by trajectories $s_0^-(x, 0, N) = u^-(x, 0, N)$ lying on the real axis. There are no trajectories $s_0^+(x, P, N)$ going to the trivial zeros.

7. THE NUMBER OF ASYMPTOTES

It is well-known [17] that the number $N(T)$ of zeros s_m of $\zeta(s)$ for which t lies in the interval of $0 < t \leq T$ can be expressed for $T \rightarrow \infty$ by

$$N(T) = \frac{T}{2\pi} \log T - \frac{1 + \log 2\pi}{2\pi} T + R(T) , \quad (30)$$

where $R(T) = O(\log T)$. According to Backlund [18] one can estimate $R(T)$ for $T > 2$ by

$$|R(T)| \leq 0.137 \log T + 0.443 \log \log T + 5.225 . \quad (31)$$

Since we found that the first 33 zeros s_m could be assigned to corresponding asymptotes $v^+(P, N)$ and $v^-(P, N)$, it would be interesting to know the number of asymptotes in the interval $0 < t \leq T$ for $T \rightarrow \infty$. As mentioned in Section 4, the imaginary part of a zero s_m which is approached by a trajectory $s_0(x, P, N)$ may differ considerably from the corresponding asymptote $v(P, N)$, so that one cannot necessarily expect a formula identical to $N(T)$.

An analytical approach to the numbers $A^\pm(T)$ of asymptotes $v^\pm(N, P)$ in $0 < t \leq T$ yields, without great difficulty, a term

$$\frac{T}{2\pi} \log T , \quad (32)$$

which is the leading term in formula (30). However, we did not succeed in finding analytically a constant for the linear term in T corresponding to formula (30). We therefore carried out a computer evaluation of the numbers $A^+(T)$ (for $P = 1, 2, \dots$, $N = 1, 2, \dots$) and $A^-(T)$ (for $P = 1, 2, \dots$, $N = 2, 3, \dots$) taking $T = 10^j$, $j = 1(1)12$, and tried to fit an expression of the form

$$A(T) = \frac{T}{2\pi} \log \frac{T}{2\pi c} \quad (33)$$

It transpires that $A^+(T)$ and $A^-(T)$ fit such a formula very well, and that, for increasing T , the values for the constant c converge to $c^+ = 2.8193038$ and $c^- = 3.0524102$, whereas for $N(T)$ we have $c = e = 2.7182818$. This means that for large T there are, in both cases, more zeros s_m than asymptotes, the excess being proportional to T , namely

$$\begin{aligned} N(T) - A^+(T) &\approx 5.8076 \times 10^{-3} T \\ N(T) - A^-(T) &\approx 1.8451 \times 10^{-2} T . \end{aligned} \quad (34)$$

For the remainder $R(T)$ in $N(T)$, one obtains from (31)

$$|R(10^{12})| < 10.5 . \quad (35)$$

It should be noted that $P = 0$ is not counted for $A^+(T)$, and that $N = 1$ is not counted for $A^-(T)$, for the reasons described in Section 4. The inclusion of these asymptotes would lead to constants $c^+ = 0.3815513$ and $c^- = 1.5262051$, respectively, which differ far more widely from e .
