Draft version November 27, 2006

ABSTRACT

We present a comprehensive description of the population synthesis code StarTrack. The original code has been significantly modified and updated. Special emphasis is placed here on processes leading to the formation and further evolution of compact objects (white dwarfs, neutron stars, and black holes). Both single and binary star populations are considered. The code now incorporates detailed calculations of all mass-transfer phases, a full implementation of orbital evolution due to tides, as well as the most recent estimates of magnetic braking. This updated version of StarTrack can be used for a wide variety of problems, with relevance to many current and planned observatories, e.g., studies of X-ray binaries (Chandra, XMM-Newton), gravitational radiation sources (LIGO, LISA), and gamma-ray burst progenitors (HETE-II, Swift). The code has already been used in studies of Galactic and extra-galactic X-ray binary populations, black holes in young star clusters, Type Ia supernova progenitors, and double compact object populations. Here we describe in detail the input physics, we present the code calibration and tests, and we outline our current studies in the context of X-ray binary populations.

Subject headings: binaries: close — stars: evolution — stars: white dwarfs, neutron — black hole physics — X-rays: binaries

1. INTRODUCTION

The StarTrack population synthesis code was initially developed for the study of double compact object mergers in the context of gamma-ray burst (GRB) progenitors (Belczynski, Bulik & Rudak 2002b) and gravitational radiation inspiral sources (Belczynski, Kalogera & Bulik 2002c, hereafter BKB02). StarTrack has undergone major updates and revisions in the last few years. With this code we are able to evolve isolated (not dynamically interacting) single stars and binaries for a wide range of initial conditions. The input physics incorporates our latest knowledge of processes governing stellar evolution, while the most uncertain aspects are parameterized to allow for systematic error analysis. During the code development, special emphasis was placed on the compact object populations: white dwarfs (WDs), neutron stars (NSs), and black holes (BHs). The input physics currently includes all major processes important for the formation and evolution of compact objects. Among other things we have developed fast procedures to treat and diagnose various types of mass transfer episodes (including phases of thermal timescale and dynamically unstable mass transfer leading to common envelopes). We also compute tidal effects on orbital evolution, angular momentum losses due to magnetic braking and gravitational radiation, as well as mass loss from stellar winds and during mass transfer phases. Rejuvenation of binary components is taken into account. The full orbital evolution of binaries is also computed, including angular momentum and mass loss. Supernovae (SNe) and compact object formation are also treated in detail.

The new version of StarTrack presented here has already been tested and used in many applications. Belczynski & Taam (2004a) studied the formation of ultrashort period X-ray binaries and they also demonstrated that the faint X-ray Galactic Center population can neither be explained by quiescent NS/BH transients nor by hard/faint wind-fed sources (Belczynski & Taam 2004b). Belczynski, Sadowski & Rasio (2004b) and Belczynski et al. (2006) developed a comprehensive description of young BH populations, which can also provide realistic initial conditions for the dynamical modeling of BHs in star clusters. Belczynski et al. (2004a) derived for the first time a synthetic X-ray luminosity function which agrees with Chandra observations of NGC 1659, and Sepinsky, Kalogera, & Belczynski (2005) explored the numbers and spatial distribution of X-ray binaries formed in young star clusters. Belczynski, Bulik & Ruiter (2005b) tested different models of Type Ia SN progenitors, arriving at the conclusion that the double degenerate scenario most easily reproduces the observed delay times between star formation and Type Ia SNe. Belczynski et al. (2005a) used StarTrack to study the gravitational radiation signal from the Galactic population of double WDs. Nutzman et al. (2004), O’Shaughnessy et al. (2005a,b,c), and Ihm, Kalogera, & Belczynski (2005) studied binary compact object populations and derived merger rates and detection rates by ground-based interferometers; they also examined BH spin magnitudes and studied the
SINGLE STELLAR EVOLUTION

In all subsequent sections we use units of $M_\odot$ for mass, $R_\odot$ for orbital separations and stellar radii, Myr for time, $L_\odot$ for bolometric luminosity, unless specified otherwise. We use $R$ and $M$ to denote stellar radius and mass, while $a, e$ represent the binary orbital parameters: semi-major axis and eccentricity, respectively. Index $i = 1, 2$ is used to mark the binary components (or single stars for consistency), or to denote an accretor and a donor in mass transfer calculations: $i = \text{acc, don}$. Roche lobe parameters are indexed with “lob”. The initially more massive (at Zero Age Main Sequence) binary component is referred to as primary, while its companion as secondary.

2.1. Overview

The evolution of single stars and non-interacting binary components have remained mostly unchanged since the last published description of the code (BKB02) and therefore we only give a brief outline here. However, we do point out the new additions and reiterate the modifications to the original formulas which were used as the base for the implementation of single star evolution in StarTrack.

To evolve single stars from the Zero Age Main Sequence (ZAMS) until remnant formation (WD, NS, BH, or a remnant-less supernova) we employ the analytic formulas of Hurley, Pols & Tout (2000). Each star is followed along an evolutionary track specific for its initial mass and metallicity. Various wind mass loss rates that vary with the stellar evolutionary stage are incorporated into the code and their effect on stellar evolution is taken into account. Once the remnant is formed, we terminate the calculations but keep track of the numbers, properties and formation times of a given type of remnant. Additionally, for white dwarf remnants we take into account their subsequent luminosity evolution, and follow cooling tracks adopted from Hurley et al. (2000).

2.2. Stellar types

We follow Hurley et al. (2000) to denote different stages of stellar evolution with an integer $K_i = 1...n$, where

- 0  – Main Sequence (MS) $M \leq 0.7 M_\odot$
- 1  – MS $M > 0.7 M_\odot$
- 2  – Hertzsprung Gap (HG)
- 3  – Red Giant Branch (RG)
- 4  – Core Helium Burning (CHeB)
- 5  – Early Asymptotic Giant Branch (EAGB)
- 6  – Thermally Pulsing AGB (TPAGB)
- 7  – Helium Main Sequence (HeMS)
- 8  – Helium Hertzsprung Gap (HeHG)
- 9  – Helium Giant Branch (HeGB)
- 10 – Helium White Dwarf (He WD)
- 11 – Carbon/Oxygen White Dwarf (CO WD)
- 12 – Oxygen/Neon White Dwarf (ONe WD)
- 13 – Neutron Star (NS)
- 14 – Black Hole (BH)
- 15 – massless remnant (after SN Ia explosion)
- 16 – Hydrogen White Dwarf (H WD)
- 17 – Hybrid White Dwarf (Hyb WD)

In addition to the star types introduced and coded by the numbers $K_i = 1...15$ in the original Hurley et al. (2000) formulas, we have introduced two new stellar types $K_i = 16, 17$. $K_i = 16$ denotes a H-rich white dwarf. Only main sequence stars less massive than about 0.7 $M_\odot$ can produce such a H-rich remnant through mass loss in a close binary system. These low-mass stars do not process a significant amount of hydrogen into helium in their cores (even in a Hubble time) and once their mass is stripped below the hydrogen burning limit (close to $\sim 0.08 M_\odot$) they become degenerate H-rich white dwarfs. These stars, although not frequently encountered in population synthesis, may become donors in the shortest-period interacting binaries. $K_i = 17$ denotes a hybrid white dwarf, with a carbon-oxygen-helium mixture in the core and a helium envelope. These objects are the remnants of naked Helium main sequence stars ($K_i = 7$) which are stripped of mass below 0.35 $M_\odot$ during Roche lobe overflow (RLOF). At that point, thermonuclear reactions stop and the star becomes degenerate (eg., Savonije, de Kool & van den Heuvel 1986).

2.3. Modifications

Several major changes to the original Hurley et al. (2000) formulas have been implemented within StarTrack.

2.3.1. Compact object masses

The remnant masses of neutron stars and black holes are calculated in a different way than originally suggested by Hurley et al. (2000). In the present version of the code we

eccentricities of double neutron stars. StarTrack was also incorporated into a simple stellar dynamics code, allowing the study of the effects of dynamical interactions on binary populations in dense star clusters. In that form it has been used for the study of binary fractions in globular clusters (Ivanova et al. 2005) and an investigation of intermediate-mass BHs in clusters and their connection to ultra-luminous X-ray sources (Blecha et al. 2005).

Among other things StarTrack has been adapted for the study of accretion powered X-ray binaries (XRBs). In forthcoming papers we will present the synthetic populations of XRBs formed in different stellar environments. We will start with young starburst galaxies, and move on to spiral and, eventually, old elliptical galaxies. In the next stage it will be possible to compare the models with rapidly improving observations of various X-ray point source populations. This will offer a new perspective to the study of several uncertain aspects of binary evolution leading to the formation of XRBs. It may also result in an independent diagnostic of star formation rates for nearby galaxies, since both the numbers and properties of XRBs are directly connected to the star formation history (see e.g., Grinn, Gilfanov & Sunyaev 2003; Gilfanov 2004; Kim & Fabiano 2004; Belczynski et al. 2005, in preparation).

In this paper we provide a detailed description of the current version of StarTrack, and we present the results of a number of tests. We describe the implementations of single star evolution in §2, binary orbit evolution in §3, stellar wind mass loss/accretion in §4, Roche lobe overflow calculations in §5, spatial velocities in §6, and the assumed distributions of initial parameters in §7. In §8 we discuss the validity of various input physics assumptions, and we compare StarTrack calculations with detailed evolutionary models and with various observations. Section §9 is dedicated to the discussion of X-ray binary modeling. In §10 we conclude with a short summary.
have further revised our prescription presented in Belczynski et al. (2002c) to include the more recent calculations of FeNi core masses and allow for the possibility of NS formation through electron capture supernovae (ECS). White dwarfs masses are calculated with the original formulas of Hurley et al. (2000), although ONe WDs are formed in a slightly narrower range since we allow for ECS NS formation (see below).

We determine the mass of a NS/BH remnant using information on the final CO and FeNi core masses, combined with the knowledge of the pre-supernova mass of the star. For a given initial ZAMS mass, the final CO core mass is obtained from the original Hurley et al. (2000) formulas, while we use the models of Timmes, Woosley & Weaver (1996) to estimate final FeNi core mass. The results of Timmes et al. (1996, see their Fig.2) show two distinctive FeNi core masses (we use models with the addition of Si shell mass), below and above initial masses of $M_{\text{zams}} \sim 18 - 19 \, M_{\odot}$. The dichotomy arises from different carbon burning (convective versus radiative) in the pre-supernova stellar core. For higher mass progenitors ($M_{\text{zams}} > 20 \, M_{\odot}$) there is a slow rise in a FeNi core mass that we approximate with a linear relation. The final FeNi core mass for a given CO core mass ($M_{\text{CO}}$) is obtained from:

$$M_{\text{FeNi}} = \begin{cases} 
1.50 & M_{\text{CO}} < 4.82 \, (M_{\text{zams}} < 18) \\
2.11 & 4.82 \leq M_{\text{CO}} < 6.31 \, (18 < M_{\text{zams}} < 25) \\
0.69 M_{\text{CO}} - 2.26 & 6.31 \leq M_{\text{CO}} < 6.75 \, (25 < M_{\text{zams}} < 30) \\
0.37 M_{\text{CO}} - 0.07 & M_{\text{CO}} \geq 6.75 \, (M_{\text{zams}} \geq 30)
\end{cases}$$

(1)

where all masses are expressed in $M_{\odot}$.

The effects of material fallback (ejected initially in the SN explosion) during the star’s final collapse are included. For the most massive stars we also allow for the possibility of a silent collapse (no supernova explosion) and direct BH formation. For solar metallicity and standard wind mass loss the compact object masses are obtained from

$$M_{\text{rem,bar}} = \begin{cases} 
\frac{M_{\text{FeNi}}}{M} & M_{\text{CO}} \leq 5 \, M_{\odot} \\
\frac{M_{\text{FeNi}} + f_{\text{fb}} (M - M_{\text{FeNi}})}{M} & 5 < M_{\text{CO}} < 7.6 \\
\frac{M_{\text{CO}}}{M} & M_{\text{CO}} \geq 7.6 \, M_{\odot}
\end{cases}$$

(2)

where $M$ is the pre-supernova mass of the star, and $f_{\text{fb}}$ is the fallback factor, i.e. the fraction (from 0 to 1) of the stellar envelope that falls back. The value of $f_{\text{fb}}$ is interpolated linearly between $M_{\text{CO}} = 5 \, M_{\odot}$ ($f_{\text{fb}} = 0$) and $M_{\text{CO}} = 7.6 \, M_{\odot}$ ($f_{\text{fb}} = 1$). The regimes of no fallback ($M_{\text{CO}} \leq 5 \, M_{\odot}$), partial fallback ($5 < M_{\text{CO}} < 7.6 \, M_{\odot}$) and direct collapse ($M_{\text{CO}} \geq 7.6 \, M_{\odot}$) are estimated from core collapse models of Fryer, Woosley & Hartmann (1999) and the analysis of Fryer & Kalogera (2001).

We also allow for NS formation through ECS (e.g., Podsiadlowski et al. 2004). Following Hurley et al. (2000) we use the He core mass at the AGB base to set the limits for the formation of various CO cores. If the He core mass is smaller than $M_{\text{chur1}}$, the star forms a degenerate CO core, and ends up forming a CO WD. If the core is more massive than $M_{\text{chur2}} = 2.25 \, M_{\odot}$ the star forms a non-degenerate CO core with subsequent burning of elements until the formation of a FeNi core which ultimately collapses to a NS or a BH. Stars with cores between $M_{\text{chur1}}$ and $M_{\text{chur2}}$ may form partially degenerate CO cores. If such a core reaches a critical mass ($M_{\text{c, crit}} = 1.08 \, M_{\odot}$; Hurley et al. 2000), it ignites CO off-center and non-explosively burns CO into ONe, forming a degenerate ONe core. If in subsequent evolution the ONe core increases its mass to $M_{\text{ocs}} = 1.38 \, M_{\odot}$ the core collapses due to electron capture on Mg, and forms NS (we will refer to a NS formed in this way as ECS NS, as opposed to a regular FeNi core collapse compact object formation). The ECS NSs are assumed to have unique masses of $M_{\text{rem,bar}} = M_{\text{ocs}}$. If the ONe core mass remains below $M_{\text{ocs}}$ the star forms a ONe WD.

Hurley et al. (2000) suggested $M_{\text{chur1}} = 1.66 \, M_{\odot}$

(3)

for neutron stars (Lattimer & Yahil 1989; see also Timmes et al. 1996), while for black holes we simply approximate the gravitational mass with

$$M_{\text{rem}} = 0.9 \, M_{\text{rem,bar}}$$

(4)

The resulting remnant mass spectrum covers a wide range of masses and is presented in Figure 1.

In summary, Helium WDs form from progenitors of initial masses in range $M_{\text{zams}} \lesssim 0.8 \, M_{\odot}$; CO WDs from $M_{\text{zams}} = 0.8 - 7 \, M_{\odot}$, and ONe WD are formed in range $M_{\text{zams}} = 7 - 7.6 \, M_{\odot}$. Neutron stars formed through ECS ($M_{\text{zams}} = 7.6 - 8.3 \, M_{\odot}$) have mass of $M_{\text{rem}} = 1.26 \, M_{\odot}$. Regular core-collapse (of FeNi cores) NS are formed with mass $M_{\text{rem}} = 1.36 \, M_{\odot}$ ($M_{\text{zams}} = 8.3 - 18 \, M_{\odot}$); $M_{\text{rem}} = 1.86 \, M_{\odot}$ ($M_{\text{zams}} = 18 - 20 \, M_{\odot}$) and for higher initial progenitor masses NSs form up to adopted maximum NS mass: $M_{\text{NS,max}}$. In our standard model we adopt $M_{\text{NS,max}} = 2.5 \, M_{\odot}$, and above $M_{\text{zams}} \gtrsim 21 \, M_{\odot}$ BHs are are formed. It is found that single stars may form BHs up to $\sim 11 \, M_{\odot}$ for solar metallicity ($Z = 0.02$) and $\sim 30 \, M_{\odot}$ for lower metallicities ($Z = 0.001 - 0.0001$), which is consistent with the current observations of the most massive BHs in Galactic X-ray transients. The initial-final mass relation described above and presented in Figure 1 holds only for single stellar evolution and for a specific metallicity ($Z = 0.02$). Effects of binary evolution, in particular mass loss/gain in RLOF, may alter the initial-final mass relation in two ways. First, a compact object may have a different mass; higher if a progenitor (or a compact object itself) accreted mass or smaller if a progenitor lost mass.
in RLOF. Second, the initial mass limits for formation of a given type of compact object are not sharp, since with binary mass loss/gain stars of various initial masses may form compact objects of a given mass and type. These limits are blurred by binary evolution.

The mass estimates of neutron stars in relativistic double neutron star binaries point to a NS formation mass of \( \sim 1.35 \, M_\odot \) (Thorsett & Chakrabarty 1999). It is also suggestive that the NS mass in Vela X-1 is \( \sim 1.9 \, M_\odot \). Since Vela X-1 is a high-mass X-ray binary, system with wind-fed accretion (small mass capture efficiency) and a massive star donor (short lifetime), the NS probably has not accumulated much mass, and the measured mass is close to its formation mass. Our adopted model for NS formation masses (Timmes et al. 1996) falls in qualitative agreement with these observations. Finally we allow compact object masses to increase through accretion in binary systems. Accretion and mass accumulation onto WDs is described in detail in § 5.7. For NS we need to adopt a maximum NS mass, over which NS collapses to BH. Such a collapse may lead to a short-hard Gamma-ray burst event. Depending on the preferred equation of state the maximum NS mass may vary in a wide range (\( \sim 2 - 3 \, M_\odot \)), and in particular may reach \( \sim 3 \, M_\odot \) if rotation is included (Morrison, Baumgarte & Shapiro 2004). At the moment the highest measured NS mass is \( 2.1 \pm 0.2 \, M_\odot \) for a millisecond pulsar in PSR J0751+1807; a relativistic binary with helium white dwarf secondary (Nice et. al. 2005). As stated above we adopt \( M_{\text{NS,max}} = 2.5 \, M_\odot \) for our standard model, but we relax this assumption in parameter studies.

### 2.3.2. Wind mass loss

The compilation of stellar wind mass loss rates presented in Hurley et al. (2000) has been expanded to include mass loss from low- and intermediate-mass main sequence stars. We have adopted the formulas of Nieuwenhuijzen & de Jager (1990) to calculate the mass loss rates for main sequence stars below \( \sim 8 \, M_\odot \). Although the mass loss from these stars is not large enough to significantly alter the evolution of a mass–losing star, it may play an important role in the formation and evolution of wind-accreting close binaries. Even with small mass transfer rates characteristic for the low- and intermediate-mass main sequence stars, the X-ray luminosities for accreting BHs and NSs are high enough to be detected in deep Chandra exposures. A number of faint point X-ray sources were discovered in the Galactic center with deep exposures (Wang, Gotthelf & Lang 2002; Muno et al. 2003), some of which may be explained in terms of wind-fed close binaries (Pfahl, Rappaport & Podsadlowski 2002a; Bleach 2002; Willems & Kolb 2003; Belczynski & Taam 2004b).

### 2.3.3. Rotational velocities

A compilation of updated observational data on rotational velocities is used to initiate the stellar spins on the ZAMS. The spin evolution is followed as detailed here for single stars and in § 3 for binary components. In order to obtain a functional form of the relation of the equatorial rotational velocity and stellar mass, we used the compilation of rotational velocities of Stauffer & Hartmann (1986) for stars in open clusters. The difference between cluster and field stars is quite small for massive stars (with a maximum difference of \( \sim 10\% \) for intermediate B-type stars), but can be as high as \( 40\% \) for stars later than F-type, with field stars having systematically lower rotational velocities.

The mean rotational velocity \( v_{\text{rot}} \) was determined from the projected velocity \( (v_{\text{rot}} \sin i) \) assuming a random distribution of angles with \( \sin i = \pi/4 \). We fitted \( v_{\text{rot}} \) as a function of stellar mass, and we obtained the following empirical functional form

\[
v_{\text{rot}} = \begin{cases} 
10.0 \frac{M_i^{-0.1}}{c+M_i^{-0.1}} & \text{if } M_i > M_0 \\
13.32 \frac{M_i^{-0.2}}{c+M_i^{-0.1}} & \text{if } M_i \leq M_0 
\end{cases}
\]

(5)

where, \( \alpha_1 = -0.035^{+0.06}_{-0.31} \), \( \alpha_2 = 0.12^{+0.09}_{-0.04} \), \( \beta_1 = 7.95^{+0.33}_{-0.31} \) and \( M_0 = 6.35^{+6.5}_{-2.1} \) (errors are at the 1 σ level). We stress that this is only an empirical functional form of the equatorial rotational velocity as a function of stellar mass. In Fig 2 we present the observational data from Stauffer & Hartmann (1986), together with the best fit function. In the bottom panel of this figure we also show the ratio of the Stauffer & Hartmann (1986) data and the model.

The spin angular momentum of a star may be expressed as

\[
J_{\text{i,spin}} = I_{\omega_{n}} = k_i M_i R_i^2 \omega_i \]

(6)

where, \( \omega_{n} = v_{\text{rot}}/R_i \) is the angular rotational velocity and the coefficient \( k_i \) varies as the star evolves and its internal structure changes (e.g., it is \( 2/5 \) for a solid sphere and \( 2/3 \) for a spherical shell). Following Hurley et al. (2000) we consider two structural components for each star: a core and an envelope. The spins of these two components may decouple in the course of evolution, although we keep them coupled in our standard model calculations. The spin angular momentum of a star is then

\[
J_{\text{i,spin}} = [k_{i,\text{env}} (M_i - M_{i,c}) R_i^2 + k_{i,\text{core}} M_{i,c} R_{i,c}^2] \omega_i \]

(7)

We use different values than Hurley at al. (2000) for the internal structure coefficient \( k_i \). For stars with no clear core-envelope structure \( (K_i = 0, 1, 7, 10, 11, 12, 13, 14, 16, 17) \) we use simple polytropic models (e.g., Lai, Rasio & Shapiro 1993) with \( n = 1.5 \) and \( n = 3 \) for low-mass and high-mass objects, respectively, giving

\[
k_{i,\text{env}} = \begin{cases} 
0.205 & M_i < 1 \, M_\odot \\
0.075 & M_i \geq 1 \, M_\odot 
k_{i,\text{core}} = 0
\end{cases}
\]

(8)

For giants with a clear separation between core and envelope \( (K_i = 2, 3, 4, 5, 6, 8, 9) \) we use detailed models of giant envelopes (Hurley et al. 2000) and for the core we apply a polytropic model with \( n = 1.5 \) to obtain

\[
k_{i,\text{env}} = 0.1, \quad k_{i,\text{core}} = 0.205 \]

(9)

Conservation of the spin angular momentum of a star is used then to determine its rotational velocity. Additional angular momentum losses from magnetic braking (see § 3.2) are also taken into account.

### 2.3.4. Convective/Radiative envelopes

Stars with convective and radiative envelopes respond differently to various physical processes (e.g., magnetic braking, tidal interactions or mass loss). Stars that have a significant convective envelope are: low-mass H-rich MS stars \( (K_i = 0, 1) \) within the mass range of 0.35 \( M_\odot - \)
where $M_{\text{ms,conv}}$ is the maximum mass for a MS star to develop a convective envelope; giant-like stars ($K_1 = 3, 5, 6, 8, 9$) independent of their mass and evolved low-mass Helium stars ($K_1 = 9$) below $M_{\text{he,conv}} = 3.0 \, M_\odot$. For stars crossing Hertzsprung Gap ($K=2$) and core helium burning stars ($K_1 = 4$ we obtained detailed models using the code described in Ivanova & Taam (2004) to check how far from Hayashi line stars cross the border between radiative and convective envelopes; stars cooler than $\log(T_{\text{eff}}) = 3.73 \pm 0.02$ have convective envelopes, while hotter stars have radiative envelopes. We have also examined the models presented by Schaller et al. (1992) for both solar metallicity and $Z = 0.001$ and have found that the above temperature cut works rather well for these two classes of stars for both metallicities. MS stars with masses below $\sim 0.35$ are fully convective. The value of $M_{\text{ms,conv}}$ depends strongly on metallicity

$$M_{\text{ms,conv}} = \begin{cases} 
1.25 & Z \geq 0.02 \\
-1532Z^2 + 55.73Z + 0.747 & 0.001 < Z < 0.02 \\
0.8 & Z \leq 0.001
\end{cases}$$

Values of $M_{\text{ms,conv}}$ in metallicity range $Z = 0.001 - 0.02$ are obtained from a fit to detailed evolutionary calculations (Ivanova 2006). All other stars are assumed to have radiative envelopes. We use the original Hurley et al. (2002) formulas to calculate the mass and depth of stellar envelopes.

### 2.3.5. Helium star evolution

We assume that low-mass evolved Helium stars ($K_1 = 9$) below $M_{\text{he,conv}} = 3.0 \, M_\odot$ (as opposed to 2.2 $M_\odot$ in Hurley et al. 2000) expand and form deep convective envelopes in their late stages of evolution (e.g., Ivanova et al. 2003; Dewi & Pols 2003). Helium stars with convective envelopes are subject to strong tidal interactions (convective tides as opposed to radiative damping, see §3.3), and if found in an interacting binary, they may alter significantly the fate of a given system. All helium stars ($K_1 = 7, 8, 9$) may be subject to stable RLOF. However, in dynamically unstable cases we assume a binary component merger in the case of a HeMS donor ($K_1 = 7$) or we follow a given system through a CE phase for evolved He star donors ($K_1 = 8, 9$ and test whether the system survives or merges. The examination of RLOF stability and development of dynamical instability are described in detail in §5).

The treatment of helium stars is important, for example, in later stages of evolution leading to double neutron star formation. The immediate consequences, leading to the formation of a new class of close double neutron stars, were discussed in Belczynski & Kalogera (2001), Belczynski, Bulik & Kalogera (2002a) and Ivanova et al. (2003). Due to significant updates of the code and new observational results on short GRBs with double neutron stars suggested as their progenitors (e.g., Fox et al. 2005) new StarTrack calculations relevant to the double neutron star formation are underway.

### 3. Binary orbital evolution

Throughout the course of binary evolution we track the changes in orbital properties. A number of physical processes may be responsible for these changes. In the general case of eccentric orbits we numerically integrate a set of four differential equations describing the evolution of orbital separation, eccentricity and component spins, which depend on tidal interactions as well as angular momentum losses associated with magnetic braking, gravitational radiation and stellar wind mass losses. For circular orbits with synchronized components, we can obtain an exact solution for the change of orbital separation using conservation of angular momentum. Losses of angular momentum and/or mass associated with RLOF events, magnetic braking and gravitational radiation are taken into account. We assume that any system entering RLOF becomes circularized and synchronized (if it had not already reached this equilibrium state before RLOF). In such a case we circularize to the periastron distance ($a_{\text{in}} = a_{\text{int}}(1-e)$, $e_{\text{in}} = 0$; and int. $f$ in mark initial and final values), and both components are synchronized to the new mean angular orbital velocity. For systems which have not been circularized and synchronized before entering RLOF there might be substantial mass loss (e.g., Hut & Paczynski 1984), and this is not taken into account in our calculations. Violent processes like SN explosions or common envelope phases are taken into account in binary orbital evolution. Also nuclear evolution of components (expansion/contraction affecting stellar spins) is considered. In what follows we describe the elements used to calculate the orbital evolution.

The orbital angular momentum of the binary and its mean angular velocity are expressed as

$$J_{\text{orb}} = \frac{M_1 M_2 \sqrt{a G (M_1 + M_2)}}{M_1 + M_2} \sqrt{1 - e^2}$$

$$\omega_{\text{orb}} = \sqrt{G (M_1 + M_2)} a^{-1.5}$$

where $G$ is the gravitational constant.

#### 3.1. Gravitational radiation

Binary angular momentum loss due to gravitational radiation is estimated for any type of binary following Peters (1964)

$$dJ_{\text{gr}} / dt = -\frac{32 G^2 M_1^2 M_2^2 \sqrt{M_1 + M_2}}{5 c^5 a^5 \sqrt{1 - e^2}} (1 + \frac{7}{8} e^2)$$

where $c$ is the speed of light. Emission of gravitational radiation causes orbital decay as well as circularization, both taken into account during the evolution of a binary system. For any given system, the merger time may be easily estimated (e.g., see eq.14 in BBK02).

#### 3.2. Magnetic Braking

Each binary component may be subject to magnetic braking, causing the decrease of the component’s rotation. In the case of a detached binary configuration magnetic braking is applied directly to the component spins, while during RLOF the effects of magnetic braking are applied to the orbit, since the components are then kept in synchronism. Three different prescriptions for magnetic braking are incorporated within the StarTrack code and may be used interchangeably for parameter studies. In what follows we provide a detailed description of the specific braking laws adopted.
Magnetic braking is applied to stars with a significant convective envelope, i.e., for low-mass H-rich MS stars, H-rich giant-like stars and cool HG and CHeB stars (see §2.3.4 for details) with the exception of low-mass evolved Helium stars for which there is not much known about magnetic fields. For fully convective MS stars ($K_1 = 0$, $M < 0.35 M_\odot$) magnetic braking may also operate, although it has been hypothesized that the braking is suppressed (Rappaport, Verbunt & Joss 1983; Zangrilli, Tout & Bianchini 1997) in order to provide an explanation of the observed period gap for cataclysmic variables. Therefore we assume that magnetic braking is not operative for fully convective stars, independent of the prescription used. Since massive core helium burning stars, more massive H-rich MS stars, and He-rich MS stars have radiative envelopes, we assume that magnetic braking does not operate in these stars. The prescription for the loss rate takes the form

$$\frac{dJ_{i,mb}}{dt} = -5.8 \times 10^{-22} M_i R_i^7 \gamma \omega_i^3$$

with parameter $\gamma = 2$ in our model calculations. However, studies based on the observations of rapidly rotating stars show that the Skumanich relation ($\dot{J} \propto \omega^3$) is inadequate in this regime and point to a weakening of magnetic braking due to saturation of the dynamo (Andronov, Pinsonneault & Sills 2003). In this case, the angular momentum loss rate takes the form

$$\frac{dJ_{i,mb}}{dt} = -8.88 \times 10^{-22} \sqrt{R_i/M_i} \begin{cases} \omega_i^3 & \omega_i \leq \omega_{crit} \\ \omega_{crit} & \omega_i > \omega_{crit} \end{cases}$$

where $i$ denotes the component for which magnetic braking is operating, $\omega_i$ [Myr$^{-1}$] is angular velocity, and $\omega_{crit}$ stands for a critical value of angular velocity above which the angular momentum loss rate enters the saturated regime. If the latter law is used, the saturation is applied only for MS stars and $\omega_{crit}$ is interpolated from Table 1 of Andronov et al. (2003).

In addition, we also include the form of magnetic braking from the results of a study by Ivanov & Taam (2003). In this latter study, an intermediate form of the angular momentum loss rate was derived ($\dot{J} \propto \omega^{1.3}$) based on a two component coronal model as applied to the observational data relating stellar activity to stellar rotation. Specifically, we adopt

$$\frac{dJ_{i,mb}}{dt} = -619.2 R_i^4 \begin{cases} \omega_i^3 / 9.45 \times 10^7 & \omega_i \leq \omega_x \\ 10^{-1.7}(\omega_i / 9.45 \times 10^7)^{1.3} & \omega_i > \omega_x \end{cases}$$

with $w_x = 9.45 \times 10^8$ Myr$^{-1}$. This law is used for the StarTrack standard model calculations.

### 3.3. Tidal Evolution

The evolution of the orbital parameters ($a, e$) as well as component spins ($\omega_i, i = 1, 2$) driven by tidal interactions of binary components is computed in the standard equilibrium-tide, weak-friction approximation (Zahn 1977, 1989), following the formalism of Hut (1981). This formalism allows us to treat binaries with arbitrarily large eccentricities. We assume that the only sources of dissipation are eddy viscosity in convective envelopes and radiative damping in radiative envelopes. Specifically, we integrate numerically the following differential equations in parallel with the stellar evolution

$$\frac{da}{dt}_{\text{tid}} = -6 F_{tid} \left( \frac{k}{T} \right) q_i (1 + q_i) \left( \frac{R_i}{a} \right)^8 \frac{\omega_i}{(1 - e_i^2)^{1/2}} \times \left( f_1 (e^2) - (1 - e^2)^{3/2} f_2 (e^2) \frac{\omega_i}{\omega_{orb}} \right)$$

$$\frac{de}{dt}_{\text{tid}} = -27 F_{tid} \left( \frac{k}{T} \right) q_i (1 + q_i) \left( \frac{R_i}{a} \right)^8 \frac{e}{(1 - e^2)^{3/2}} \times \left( f_3 (e^2) - \frac{1}{15} (1 - e^2)^{3/2} f_4 (e^2) \frac{\omega_i}{\omega_{orb}} \right)$$

$$\frac{d\omega_i}{dt}_{\text{tid}} = 3 F_{tid} \left( \frac{k}{T} \right) \frac{q_i^2}{r_{i,gyr}^2} \left( \frac{R_i}{a} \right)^6 \frac{\omega_i}{(1 - e_i^2)^{3/2}} \times \left( f_5 (e^2) - (1 - e^2)^{3/2} f_6 (e^2) \frac{\omega_i}{\omega_{orb}} \right)$$

where

$$f_1 (e^2) = 1 + \frac{31}{10} e^2 + \frac{255}{10} e^4 + \frac{185}{19} e^6 + \frac{25}{64} e^8$$

$$f_2 (e^2) = 1 + \frac{16}{5} e^2 + \frac{20}{3} e^4 + \frac{3}{16} e^6$$

$$f_3 (e^2) = 1 + \frac{15}{6} e^2 + \frac{15}{8} e^4 + \frac{3}{64} e^6$$

$$f_4 (e^2) = 1 + \frac{2}{15} e^2 + \frac{2}{7} e^4$$

$$f_5 (e^2) = 1 + 3 e^2 + \frac{8}{3} e^4$$

and $r_{i,gyr}$ is the gyration radius and is defined by $I_i = M_i r_{i,gyr}^2 R_i^2$, with $I_i$ denoting the moment of inertia of a given binary component. Here the mass ratio is defined as follows,

$$q_i = \begin{cases} M_2 / M_i & i = 1 \\ M_i / M_2 & i = 2 \end{cases}$$

The quantity $(k/T)_i$ is the ratio of the apsidal motion constant $k$ (which depends on the interior structure of the star) over the timescale $T$ of tidal dissipation. Following Hurley, Tout & Pols (2002), we calculate that constant for either the equilibrium tide with convective damping ($((k/T)_{i,con})$ or the dynamical tide with radiative damping ($((k/T)_{i,rad})$. Radiative damping is applied to stars with radiative envelopes: MS stars with mass above $M_{\text{env,conv}}$, CHeB stars with mass above $7 M_\odot$, massive evolved He stars and all He MS stars. For all other stars, convective damping is applied (see §2.3.4 for details on convective/radiative envelopes). We do not calculate tides on stellar remnants, e.g., on WDs ($K_1 \geq 10$).

The constant for convective damping is obtained from

$$\left( \frac{k}{T} \right)_{i,con} = \frac{2 f_{i,conv} M_{i,env}}{21 \tau_{i,conv} M_i} \text{yr}^{-1}$$

where $M_{i,env}$ is the mass contained in the convective envelope of component $i$. The eddy turnover time $\tau_{i,conv}$ is calculated as

$$\tau_{i,conv} = 0.431 \left[ \frac{M_{i,env} R_{i,env} (R_i - \frac{1}{2} R_{i,env})}{3 L_i} \right]^{1/3} \text{yr}$$
with $R_{i,\text{env}}$ denoting the depth of the convective envelope and $L_i$ the bolometric luminosity of a given component (Rasio et al. 1996).

The numerical factor $f_{i,\text{conv}}$ is defined as

$$f_{i,\text{conv}} = \min \left[ 1, \left( \frac{P_{1,\text{tid}}}{2\tau_{i,\text{conv}}} \right)^2 \right]$$  \hspace{1cm} (23)

with the tidal pumping timescale $P_{1,\text{tid}}$ defined as

$$\frac{1}{P_{1,\text{tid}}} = \left| \frac{1}{P_{\text{orb}}} - \frac{1}{P_{i,\text{spin}}} \right|$$  \hspace{1cm} (24)

where $P_{\text{orb}}$ and $P_{i,\text{spin}}$ are the binary orbital period and the spin period of component $i$, respectively. This factor represents the reduction in the effectiveness of eddy viscosity when the forcing period is less than the turnover period of the largest eddies (Goldreich & Keeley 1977).

The constant for radiative damping is calculated from

$$\left( \frac{k}{T} \right)_{i,\text{rad}} = 1.9782 \times 10^4 \sqrt{\frac{M_i R_i^2}{a^3}} (1 + q_i)^{5/6} E_2 \text{yr}^{-1}$$  \hspace{1cm} (25)

where a second-order tidal coefficient $E_2 = 1.592 \times 10^{-9} M_i^{2.84}$ was fitted (Hurley et al. 2000) to values given by Zahn (1975).

Finally, we have introduced an additional scaling factor $F_{\text{tid}}$ in the evolution equations (eq. 17, 18, 19) which we normally set to:

$$F_{\text{tid}} = \begin{cases} F_{\text{tid,con}} = 50 & \text{convective env.} \\ F_{\text{tid,rad}} = 1 & \text{radiative env.} \end{cases}$$  \hspace{1cm} (26)

and the distinction between the stars with convective and radiative envelopes is given in §2.3.4. This factor makes tidal forces (both in case of convective and radiative damping) more effective than predicted by the standard Zahn theory. The choice of this specific value of $F_{\text{tid}}$ is a result of our calibration against the cutoff period for circularization of binaries in M67 and from the orbital decay of the high mass X-ray binary LMC X-4 (for details see §8.2).

The orbital angular momentum change associated with tides is calculated from

$$\frac{dL_{i,\text{tid}}}{dt} = 3 F_{\text{tid}} I_i \left( \frac{3}{5} \right) \frac{q_i^2}{r_{i,\text{gyr}}^3} \left( \frac{R_i}{a} \right)^6 \left( \frac{\omega_{\text{orb}}}{(1-e^2)^3} \right) \times \left( f_2(e^2) - (1 - e^2)^{3/2} f_5(e^2) \right)$$  \hspace{1cm} (27)

and the change of binary parameters is calculated with eqs. 17, 18, 19.

Pre-main sequence tidal synchronization and circularization. We also allow for pre-MS tidal interactions. Since we do not follow pre-MS evolution, all binaries with orbital periods shorter than 4.3d (Mathieu et al. 1992) are simply assumed to have circularized and all binary components to have synchronized by the time they reach the ZAMS. For binaries with longer orbital periods we apply our assumed distribution of initial eccentricities (see §7) and initial rotational velocities for binary components (see §2.3.3).

\textit{Darwin instability.} One important consequence of tidal interactions in massive binaries is the possible occurrence of the Darwin instability (e.g., Lai et al. 1993). When the more massive component is spinning slowly compared to the orbital rate of its companion, tidal forces will tend to spin it up, leading to loss of orbital angular momentum (orbital decay). Usually this orbital decay will stop when synchronization is established. However, if, in the synchronized state, more than a third of the total binary angular momentum would be in the component spins, then synchronization can never be reached and the components will continue to spiral in. We follow this process until one of the binary components overflows its Roche lobe. The ensuing mass transfer may stabilize the orbital decay, and the system is then followed through this stable RLOF phase. In cases where the RLOF is found to be dynamically unstable (§5.1 and §5.2) the system goes through a CE phase leading either to a merger, or further orbital decay with envelope ejection (§5.4).

3.4. Mass and Angular Momentum Loss from Binaries

Mass lost from the binary components in stellar winds carries angular momentum, in turn affecting the orbit through tidal coupling. Similarly, during RLOF, some of the transferred material and its associated angular momentum may be lost from the system. In this section we consider the amount of angular momentum loss associated both with stellar winds and RLOF phases. However, for RLOF we only consider here dynamically stable phases, while the change of the orbit following unstable RLOF (common envelope events) is described in §5.4.

For stellar winds we assume spherically symmetric mass loss, which carries away the specific angular momentum of the mass–losing component (Jeans mode mass loss). The corresponding change of the orbit (Jeans-mode mass loss) is calculated from

$$a (M_1 + M_2) = \text{const.}$$ \hspace{1cm} (28)

The above approach holds for circular orbits, however the change in binary separation $a$ is similar for eccentric orbits (Vanbeveren, Van Rensbergen & De Loore 1998, see p. 124).

In the case of stable RLOF with compact accretors (WD, NS, BH; $K_{\text{acc}} = 10, 11, 12, 13, 14, 16, 17$) we limit (although this assumption may be relaxed) accretion to the Eddington critical rate

$$\dot{M}_{\text{edd}} = 2.088 \times 10^{-3} \frac{R_{\text{acc}}}{\epsilon (1 + X)} \text{M}_\odot \text{yr}^{-1}$$ \hspace{1cm} (29)

and the corresponding critical Eddington luminosity may be expressed as

$$L_{\text{edd}} = \epsilon \frac{G M_{\text{acc}} \dot{M}_{\text{edd}}}{R_{\text{acc}}}$$ \hspace{1cm} (30)

where $R_{\text{acc}}$ denotes the radius at which the accretion onto compact object takes place (a NS or a WD radius, and three Schwarzschild radii for a BH). $X$ denotes the composition of accreted material (0.7 for the H-rich material, and 0.6 for all other compositions), and $\epsilon$ gives the conversion efficiency of gravitational binding energy to radiation.
associated with accretion onto a WD/NS (surface accretion $\epsilon = 1.0$) and onto a BH (disk accretion $\epsilon = 0.5$). We also note that above some critical (very high) accretion rate, nuclear burning will start on the WD surface. This can be much more radiatively efficient than the gravitational energy release and the above relations break down. If the mass transfer rate is higher than $M_{\text{edd}}$ we expect the excess material to leave the system from the vicinity of the accreting object and thus to carry away the specific angular momentum of the accretor. The angular momentum loss associated with a given systemic mass loss in a RLOF phase is obtained from

$$dJ_{\text{RLOF}}/dt = R_{\text{com}}^2 w_{\text{orb}}(1 - f_a)M_{\text{don}}$$  (31)

where $R_{\text{com}} = aM_{\text{don}}/(M_{\text{don}} + M_{\text{acc}})$ is the distance between the accretor and binary center of mass, and $M_{\text{don}}$ is the mass transfer rate (donor RLOF rate, see eq. 22). The $f_a$ fraction of material transferred from the donor is accreted on the compact object. If mass transfer is sub-Eddington then $f_a = 1$ (conservative), otherwise it is $f_a = M_{\text{edd}}/M_{\text{don}}$ (non-conservative). Here we assume that the radiative efficiency is not a function of the mass transfer rate. Some work has suggested that at high transfer rates, flows onto black holes may become radiatively inefficient as photons are trapped in the flow and advected into the black hole (see e.g., Abramowicz et al. 1988), or that substantially super-Eddington accretion may be possible in non-spherical accretion flows (e.g., Begelman 2002). In the current version of the code, we do not consider these possibilities.

For all other, non-degenerate accretors ($K_{\text{acc}} = 0,1,2,3,4,5,6,7,8,9$) we assume a non-conservative evolution through stable RLOF, with part of the mass lost by the donor accreted onto the companion ($f_a$), and the rest $(1 - f_a)$ leaving the system with a specific angular momentum $j_{\text{loss}}$ expressed in units of $2\pi a^2/F_{\text{orb}}$ (see Podsiadlowski, Joss & Hsu 1992). The angular momentum loss is then estimated from

$$dJ_{\text{RLOF}}/dt = j_{\text{loss}}M_{\text{don}}^2 + M_{\text{acc}}(1 - f_a)M_{\text{don}}$$  (32)

For our standard model calculation we adopt $j_{\text{loss}} = 1$, and $f_a = 0.5$ (half of the transferred mass lost from system, e.g. Meurs & van den Heuvel 1989). However, we note that the amount of mass lost (as well as the specific angular momentum with which the mass is lost from the binary) may change from case to case. Ideally, one would like to know the details of mass transfer/loss for all potential binary configurations, and change $j_{\text{loss}}$ and $f_a$ according to the types of interacting stars as well as binary properties. Since, such predictions or understanding are not available, we treat $j_{\text{loss}}$ and $f_a$ as parameters, which are applied evenly to all the stars in a given simulation.

4. WIND MASS LOSS/ACCRETION IMPLEMENTATION

We adopt the compilation of mass loss rates from Hurley et al. (2000). We have further extended the original formulas to include winds from low- and intermediate-mass MS stars. The structure of the star (and its subsequent evolution) in response to stellar wind mass loss is self-consistently taken into account with the Hurley et al. (2000) evolutionary formulas. The most important effects include possible removal of the H-rich envelope of a massive star or a more gradual nuclear evolution with decreasing mass. The effects of wind mass loss from binary components on the orbital parameters are also accounted for (see §3.4).

The effects of mass increase of binary components due to accretion from the companion winds are neglected. Either the wind accretion rates are very low or the high wind accretion phases do not last for long, which does not translate into significant mass increase of a companion star. However, we estimate the wind accretion rates onto NSs and BHs since it may give rise to bright X-ray emission (see §9).

The wind accretion rate is calculated in the general case of eccentric orbits, i.e. we obtain accretion rate (and accretion luminosity) for a specified position on the orbit, or we integrate over a specific part of the orbit (e.g., corresponding to the exposure time of given observations). This may be of importance for eccentric wind-fed binaries, e.g., high mass X-ray binaries (see §9.2). We have also implemented an orbital-averaged solutions. The two solutions may be adopted as required for a given project or analysis.

4.1. General Eccentric Orbit Case

We follow the Bondi & Hoyle (1944) accretion model to calculate the accretion from stellar wind. As an approximation we may express (Boffin & Jorissen 1988) the accretion rate as

$$\dot{M}_{\text{acc, wind}} = \alpha_{\text{wind}} \frac{2\pi (GM_{\text{acc}}^2)}{(V_{\text{rel}}^2 + c_{\text{wind}}^2)^{3/2}}$$  (33)

where $\alpha_{\text{wind}} = 1.5$ is the accretion efficiency in the Bondi–Hoyle model, although it may be as low as 0.05 in some specific cases (e.g., see hydrodynamical simulations of Theuns, Boffin & Jorissen 1996 for Barium star formation). $c_{\text{wind}}$ is the wind sound speed, and $V_{\text{rel}}$ is the relative velocity of the wind with respect to the accreting star. The local (undisturbed) density of the wind matter $\rho$ in the vicinity of the accreting object may be calculated in a steady spherically symmetric case from

$$\dot{M}_{\text{don, wind}} = -4\pi r^2 \rho V_{\text{wind}}$$  (34)

where $\dot{M}_{\text{don, wind}}$ is the wind mass loss rate form the donor, $r$ is the instantaneous distance between the two stars, and $V_{\text{wind}}$ is the wind velocity. We assume that the wind flow is supersonic ($V_{\text{rel}} \gg c_{\text{wind}}$) so that $c_{\text{wind}}^2$ may be dropped from eq. 33. We introduce $\rho$ (expressed through eq. 34) into eq. 33 to obtain

$$\dot{M}_{\text{acc, wind}} = -\alpha_{\text{wind}} \frac{(GM_{\text{acc}}^2)}{2V_{\text{rel}}^2 V_{\text{wind}}^2} M_{\text{don, wind}}$$  (35)

The accretion rate calculated with eq. 35 varies as the accreting object moves in its orbit around the mass–losing star. The relative distance $r$ of the two stars is obtained through the Kepler equation for a given orbit. Obviously $r$ is a function of orbital position. The vector of the relative velocity $V_{\text{rel}}$ is defined as

$$\vec{V}_{\text{rel}} = \vec{V}_{\text{acc, orb}} + \vec{V}_{\text{wind}}$$  (36)

where $\vec{V}_{\text{acc, orb}}$ denotes the instantaneous velocity of the accretor on the orbit relative to the mass losing star, and
is readily obtained for a given position through the Kepler equation. The direction of the wind velocity vector \( \vec{V}_{\text{wind}} \) follows the vector pointing toward the accretor on its relative orbit around the mass–losing star. We set the wind velocity proportional to the escape velocity from the surface of the mass–losing star

\[
V_{\text{wind}}^2 = 2\beta_{\text{wind}} \frac{GM_{\text{don}}}{R_{\text{don}}},
\]

and vary \( \beta_{\text{wind}} \) with the spectral type of the mass–losing star. For extended \((R_{\text{don}} > 900 R_\odot)\) H-rich giants \((K_{\text{don}} = 2, 3, 4, 5, 6)\) slow winds are assumed \( \beta_{\text{wind}} = 0.125 \). For the most massive MS stars \((> 120 M_\odot)\) \( \beta_{\text{wind}} = 7 \), for low mass MS stars \((< 1.4 M_\odot)\) \( \beta_{\text{wind}} = 0.5 \) and the value of \( \beta_{\text{wind}} \) is interpolated in-between. For He-rich stars \((K_{\text{don}} = 7, 8, 9)\); \( \beta_{\text{wind}} = 7 \) for \( M_{\text{don}} > 120 M_\odot \), \( \beta_{\text{wind}} = 0.125 \) for \( M_{\text{don}} < 10 M_\odot \), and is interpolated in-between. The values of \( \beta_{\text{wind}} \) follow from the observations of wind velocities for different type of stars (Lamers, Snow & Lindholm 1995; Kucinskas 1999) and are adopted from the discussion of wind properties in Hurley et al. (2002).

4.2. Orbit-averaged Case

We use eq. 35 to obtain the orbit-averaged accretion rate. The wind velocity vector is assumed to be perpendicular to the orbital speed vector (as on a circular orbit), i.e., \( V_{\text{rel}}^2 = V_{\text{acc, orb}}^2 + V_{\text{wind}}^2 \). The wind velocity is taken from eq. 37. The orbital velocity of the accretor is taken to be constant and is obtained from the circular orbit approximation \( V_{\text{acc, orb}}^2 = GM_{\text{acc}} + M_{\text{don}})/a \). Finally, \( 1/r^2 \) is substituted in eq. 35 with its mean value over one orbital revolution, i.e., \( 1/(a^2\sqrt{1-e^2}) \) to obtain

\[
\dot{M}_{\text{acc, wind}} = -\frac{F_{\text{wind}}}{\sqrt{1-e^2}} \left( \frac{GM_{\text{acc}}}{V_{\text{wind}}^2} \right)^2 \frac{\alpha_{\text{wind}} \dot{M}_{\text{don, wind}}}{2a^2 (1 + V_{\text{wind}}^2)^{3/2}}
\]

(38)

where \( F_{\text{wind}} \) is a parameter (see below) and \( V_{\text{wind}}^2 = V_{\text{acc, orb}}^2/V_{\text{wind}}^2 \).

For highly eccentric orbits, the averaged (over one orbit) accretion rate calculated with the eq. 35 may exceed the companion mass loss rate. This is a direct result of the orbital averaging used above. To avoid this we follow Hurley et al. (2002; §2.1) and adopt \( F_{\text{wind}} \) such that \( \dot{M}_{\text{acc, wind}} \) never exceeds \( 0.8 \dot{M}_{\text{don, wind}} \).

5. ROCHE LOBE OVERFLOW CALCULATIONS

Different physical processes may be responsible for driving RLOF. In the following we describe the treatment of mass loss and mass accretion in our model.

5.1. Mass Transfer/Accretion Rate

For any binary system during RLOF phases with a non-degenerate donor \((K_{\text{don}} < 10)\) we calculate the radius mass exponents for the donor and its Roche lobe

\[
\zeta_{\text{don}} = \frac{\partial \ln R_{\text{don}}}{\partial \ln M_{\text{don}}}
\]

(39)

\[
\zeta_{\text{lob}} = \frac{\partial \ln R_{\text{don, lob}}}{\partial \ln M_{\text{don}}}
\]

(40)

and we estimate the change of donor radius with time due to its nuclear evolution as

\[
\zeta_{\text{evl}} = \frac{\partial \ln R_{\text{don}}}{\partial t}
\]

(41)

The above derivatives are calculated numerically with the use of the analytic single star formulas of Hurley et al. (2000). The time derivative of the stellar radius \( (\zeta_{\text{evl}}) \) is obtained directly from the single star formulas, since the radius of a given star is tracked in time. To obtain response of the donor to mass loss \( (\zeta_{\text{don}}) \) we calculate the response of the star to an instantaneous (over a timespan of only 1 yr, a time interval unimportant for stellar evolution) mass loss through (artificially) increased wind mass loss. Finally, the Roche lobe exponent is obtained by removing 1% of the donor mass, part of which is transferred to the accretor and the rest is lost with the specific angular momentum of the accretor from the binary (see §3.4); a new Roche lobe radius and the numerical derivative are then readily calculated.

RLOF may be driven by different physical processes; angular momentum losses connected to magnetic braking and gravitational radiation or expansion due to nuclear evolution. We do not include tides as we assume that binary is circular and synchronized during RLOF. The timescales for magnetic braking, and gravitational radiation are calculated from

\[
\tau_{\text{mb}} = -\frac{J_{\text{orb}}}{dJ_{\text{don, mb}}/dt + dJ_{\text{acc, mb}}/dt}
\]

(42)

\[
\tau_{\text{gr}} = -\frac{J_{\text{orb}}}{dJ_{\text{gr}}/dt}
\]

(43)

where expressions for \( dJ_{\text{gr}}/dt \), \( dJ_{\text{don, mb}}/dt \), are given in \S 3.1, and \S 3.2 respectively.

If RLOF is driven by the combination of angular momentum losses changing the orbit and nuclear evolution of the donor we then calculate the mass transfer rate from

\[
\dot{M}_{\text{eq}} = -\frac{\zeta_{\text{evl}} + \zeta_{\text{don}} + \zeta_{\text{lob}}}{\zeta_{\text{don}} - \zeta_{\text{lob}}} \dot{M}_{\text{don}}
\]

(44)

and the corresponding mass transfer timescale

\[
\tau_{\text{eq}} = -\frac{\dot{M}_{\text{don}}}{\dot{M}_{\text{eq}}}
\]

(45)

Additionally we estimate the thermal timescale for the donor following Kalogera & Webbink (1996) from

\[
\tau_{\text{th}} = \frac{30 \times \dot{M}_{\text{don}}^2}{R_{\text{don}} L_{\text{don}}}
\]

(46)

and the mass transfer rate on the thermal timescale

\[
\dot{M}_{\text{th}} = -\frac{\dot{M}_{\text{don}}}{\tau_{\text{th}}}
\]

(47)

In the case of stable RLOF, \( \tau_{\text{eq}} \geq \tau_{\text{th}} \), a donor is in thermal equilibrium, and we use eq. 47 to calculate the mass transfer rate. Otherwise, for \( \tau_{\text{eq}} \leq \tau_{\text{th}} \), RLOF proceeds on the thermal timescale and we evolve a given system calculating the mass transfer rate from eq. 47. We follow the timescales of the donor as it evolves through RLOF, and apply the appropriate mass loss rate. For example,
a massive donor may be transferring mass on the thermal timescale at first, but once it loses a fraction of its mass, the mass transfer becomes stable and RLOF proceeds on the timescale defined by $\tau_{eq}$. However, in some cases the RLOF is so rapid that it may eventually lead to a dynamical instability. Once $M_{eq}$ changes sign and becomes positive, the donor loses its equilibrium, and the system evolves either on the thermal or dynamical timescale. In this case a special diagnostic diagram is used (see below) to decide which of the two timescales is relevant. We also allow for the development of a delayed dynamical instability, which may occur for stars with a radiative envelope, but with a deep convective layer. Dynamical instability during RLOF leads to a spiral-in of the binary components and common envelope evolution (CE). We follow the CE phase to determine whether the binary survives (ejection of the envelope at the expense of orbital energy) or if a merger of the binary components (single star formation) occurs.

The following summarizes the calculation of the RLOF mass transfer rates

\[
M_{\text{don}} = \begin{cases} 
\text{CE/merger} & M_{\text{don}} > q_{\text{ddi}} \times M_{\text{acc}} \\
M_{\text{eq}} & M_{\text{eq}} < 0 \text{ and } \tau_{eq} > \tau_{th} \\
M_{\text{th}} & M_{\text{eq}} < 0 \text{ and } \tau_{eq} \leq \tau_{th} \\
M_{\text{th/CE/merger}} & \text{diagnostic diagram}
\end{cases}
\]

(48)

where we additionally assume that above some critical mass ratio ($q_{\text{ddi}} = M_{\text{don}}/M_{\text{acc}}$) the binary system will evolve toward delayed dynamical instability (Hjellming & Webbink 1987), leading to rapid inspiral and CE evolution. For H-rich stars Hjellming (1989) gives a range $q_{\text{ddi}} = 2-4$ depending on the evolutionary state of a donor, while Ivanova & Taam (2004) obtain $q_{\text{ddi}} = 2.9 - 3.1$. In our standard model calculations we adopt $q_{\text{ddi}} = 3$ for H-rich stars ($K_1 = 0, 1, 2, 3, 4, 5, 6$). For He-rich stars we adopt critical mass ratios from Ivanova et al. (2003); $q_{\text{ddi}} = 1.7$ for HeMS stars ($K_1 = 7$), while $q_{\text{ddi}} = 3.5$ for evolved He stars ($K_1 = 8, 9$). We note that the study of Ivanova et al. (2003) was targeted for He stars with NS accretors only. However, we adopt their values for systems with He star donors and arbitrary accretors, since detailed models for arbitrary accretors are not available. Also, dynamical instability may be encountered if the trapping radius of the accretion flow exceeds the Roche lobe radius of the accretor ($\tau_{ddi}$). Additionally, we consider the case of spiral-in in the case of the Darwin instability, where the components’ spin angular momentum is comparable to the orbital angular momentum ($\tau_{3.3}$).

For the donor stars without a well defined core-envelope structure ($K_{\text{don}} = 0, 1, 7, 10, 11, 12, 16, 17$) we assume that dynamical instability during RLOF always leads to a merger. The same is assumed for the donors in the Hertzsprung gap ($K_{\text{don}} = 2$) as there is no clear entropy jump at the core-envelope transition (Ivanova & Taam 2004; Belczynski & Taam 2004a). In the case of a merger a single stellar object is formed. However, we do not follow its evolution here, as the chemical composition and structure of merged remnants is not well understood and certainly is different than normal stars. This may lead to an underestimate of our synthetic supernovae rate, since potentially some merger products are massive enough to evolve and explode as Type II or Ib/c SNe. For H-rich and He-rich giant-like donors ($K_{\text{don}} = 3, 4, 5, 6, 8, 9$) we follow CE evolution, and assuming ejection of the entire donor envelope, we calculate the most probable outcome with conservation of energy (see §5.4). If RLOF is encountered for a system with an evolved Helium star donor ($K_1 = 8, 9$), then it is found that for low donor masses ($\leq 4 - 5 M_\odot$) RLOF is stable (although it may proceed at very high rates) while for higher donor masses it leads to a CE phase (e.g., see Ivanova et al. 2003). The survival of the binary then depends on the donor properties (e.g., envelope binding energy, its mass, binary separation).

The mass accretion rate in a dynamically stable RLOF is calculated from

\[
M_{\text{acc}} = f_s M_{\text{don}}
\]

(49)

where $M_{\text{don}}$ is the donor RLOF mass transfer rate (see eq. 48). The parameter $f_s$ denotes the fraction of the transferred mass which is accreted, while the rest ($1 - f_s$) is ejected from the system (see §3.4). Mass accretion in dynamically unstable cases (CE events) is calculated only for NS and BH accretors, since only then significant accretor mass gain may be expected in spite of the very short timescales (for details see BKB02).

5.2. Diagnostic Diagram for Rapid Mass Transfer

The aforementioned diagnostic diagram is shown in Fig 2. Once RLOF proceeds on the thermal timescale, and the donor is no longer in thermal equilibrium, we do not have proper stellar models to use and calculate the donor properties (e.g., RLOF rate). Therefore, we use an approximate method and calibrate it based on the results from detailed stellar evolutionary and mass transfer calculations, which are not limited to stars in thermal equilibrium. When the donor loses its equilibrium, we use the stellar and binary properties to predict whether the system will evolve through the phase of thermal mass transfer and the donor will regain its equilibrium, or the RLOF will become dynamically unstable and will eventually lead to CE evolution. We plot the donor Roche lobe radius versus decreasing donor mass under the assumption that mass transfer is non-conservative and proceeds on the thermal timescale (see eqs. 46 and 47). For NS/BH accretors the accretion rate is limited by the Eddington rate, while for all other accretors, a fraction $f_s$ of transferred material is accreted. The associated specific angular momentum loss is described in §3.4. As the mass of the donor decreases with mass transfer the Roche lobe first shrinks and then at some critical mass ratio ($q_{\text{low}}$), it starts expanding again (see the solid line on the top panel, Fig. 2). If the mass ratio at the moment the star loses its equilibrium $q_{\text{in}}$ is not greatly different than $q_{\text{low}}$ we expect that the donor may regain the equilibrium when the system is expanding. The dashed line arrow in Figure 2 shows the expected behavior of the donor when it loses its equilibrium. If the system does not evolve into a CE phase then we expect the donor to regain its equilibrium at the position indicated by the arrow. Of course this is just an approximation, since, as the donor evolves, the radius-mass exponent changes. We use a number of published (Tauris & Savonije 1999; Wellstein & Langer 1999; Wellstein, Langer & Braun 2001; Dewi & Pols 2003) and unpublished (N. Ivanova 2004, private communication) detailed calculations to calibrate the diagnostic diagram. Based on these studies we find that a
CE phase ensues if

\[
CE \begin{cases} 
q_{\text{int}} \geq 1.2 \ q_{\text{low}} & K_{\text{don}} = 2, 3, 4, 5, 6 \\
q_{\text{int}} \geq 2.0 \ q_{\text{low}} & K_{\text{don}} = 0, 1, 7, 8, 9 
\end{cases}
\] (50)

Otherwise the system is evolved through RLOF on the donor’s thermal timescale.

5.3. Thermal Timescale Mass Transfer

Once a binary is identified as a thermal timescale RLOF system, we assume that the mass transfer rate remains constant throughout the entire episode. We calculate the rate using eq. (44) where we use properties corresponding to the time the donor loses its thermal equilibrium. This may be justified by the following: (i) thermal mass transfer rates have been shown to be rather constant within a factor of \(\sim 2 - 3\) (Paczynski 1971), (ii) since the rates are calculated at the time the star loses equilibrium, it is a good approximation (and the best possible with only equilibrium stellar models being available) for the short lived phase of thermal mass transfer that follows.

In the bottom panel of Figure 3 we show an example calculation through a thermal RLOF phase, followed with a slower (driven by nuclear evolution) RLOF period after the donor has regained its thermal equilibrium. The specific system was chosen to match the RLOF calculation of Wellstein et al. (2001) for a 16 M\(_{\odot}\) and 15 M\(_{\odot}\) binary with an initial period of 8 days. The RLOF starts when the primary evolves off the main sequence and crosses the Hertzsprung Gap. Mass transfer initially proceeds on a thermal timescale at a very high rate (\(\sim 2.8 \times 10^{-3} \ M_{\odot} \ yr^{-1}\)), then the star regains its equilibrium and the RLOF rate decreases with time by more than order of magnitude (\(\sim 10^{-4} \ M_{\odot} \ yr^{-1}\)). Our calculation can be directly compared to Wellstein et al. (2001): see their Figure 4, left panel. Their detailed stellar evolution calculation shows a thermal RLOF rate of \(\sim 10^{-3} \ M_{\odot} \ yr^{-1}\), followed by a slower RLOF phase characterized by rates of \(\sim 10^{-4} \ M_{\odot} \ yr^{-1}\), very similar to what we find with our simplified prescription. Our RLOF phase lasts about twice as long as that of Wellstein et al. (2001), who in contrast to our calculation assumed conservative evolution and did not include effects of tidal spin-orbit interactions. We choose not to modify our standard model assumptions (e.g., neglect tidal interactions) for comparisons, and therefore emphasize some differences with previous calculations. More comparisons of RLOF sequences are presented in § 8.1.

5.4. Dynamical Instability and Common Envelopes

Dynamically unstable mass transfer may be encountered in a number of ways. Most often it is the direct consequence of stellar expansion during rapid nuclear evolution phases. However, loss of orbital angular momentum (e.g., via magnetic braking, gravitational radiation, or tides) may also lead to dynamical instability.

Additionally, we allow a system to evolve into a CE phase if the trapping radius of the accretion flow exceeds the Roche lobe radius of the accreter. The trapping radius is defined as (Begelman 1979)

\[
R_{\text{trap}} = \frac{M_{\text{don}}}{M_{\text{edd}}} R_{\text{acc}} \lambda R_{\text{don,lob}}
\] (51)

Following King & Begelman (1999) and Ivanova et al. (2003) we check whether the mass transfer rate exceeds a critical value above which the system is engulfed in a CE

\[
\dot{M}_{\text{trap}} = 2 \times \dot{M}_{\text{edd}} \frac{R_{\text{acc, lob}}}{R_{\text{acc}}}
\] (52)

where \(R_{\text{acc, lob}}\) is the accretor Roche lobe radius, and \(\dot{M}_{\text{edd}}\) is the Eddington critical accretion rate (see eq. (23)).

Below we present two different implementations of the orbital contraction calculation during CE that are incorporated in StarTrack.

Standard Energy Balance Prescription. If dynamical instability is encountered a binary may enter a CE phase. We use the standard energy equation (Webbink 1984) to calculate the outcome of the CE phase

\[
\alpha_{\text{ce}} \left( \frac{GM_{\text{don, fin}}M_{\text{acc}}}{2A_{\text{fin}}} - \frac{GM_{\text{don, int}}M_{\text{acc}}}{2A_{\text{int}}} \right) = \frac{GM_{\text{don, int}}M_{\text{don, env}}}{\lambda R_{\text{don, lob}}}
\] (53)

where, \(M_{\text{don, env}}\) is the mass of the donor envelope ejected from the binary, \(R_{\text{don, lob}}\) is the Roche lobe radius of the donor at the onset of RLOF, and the indices int, fin denote the initial and final values, respectively. The parameter \(\lambda\) is a measure of the central concentration of the donor (de Kool 1990; Dewi & Tauris 2000). The right hand side of equation (53) expresses the binding energy of the donor’s envelope, the left hand side represents the difference between the final and initial orbital energy, and \(\alpha_{\text{ce}}\) is the CE efficiency with which orbital energy is used to unbind the stellar envelope. If the calculated final binary orbit is too small to accommodate the two post-CE binary components then a merger occurs. In our calculations, we combine \(\alpha_{\text{ce}}\) and \(\lambda\) into one CE parameter, and for our standard model, we assume that \(\alpha_{\text{ce}} \times \lambda = 1\). This is for all but evolved naked Helium stars (\(K_1 = 8.9\)) for which we adopt \(\alpha_{\text{ce}} = 1.0\) and \(\lambda = 0.3 R_i^{-0.8}\), where \(R_i\) is radius of Helium star in solar radii. The relation for \(\lambda\) was obtained with Ivanova’s (2003) evolutionary code. If a compact object spirals in the common envelope it may accrete significant amounts of material because of hyper-critical accretion (Blondin 1986; Chevalier 1989, 1993; Brown 1995). We have incorporated a numerical scheme to include the effects of hyper-critical accretion on NSs and BHs in our standard CE prescription (for details see BKB02). Compact objects gain, on average, several tenths of solar mass in CE if hyper-critical accretion is allowed. However, we also allow for evolution with no hyper-critical accretion following recent results of accretion flow calculations with geometry specific for compact object moving through common envelope. These calculations indicate that accretion can be limited to only 0.01 M\(_{\odot}\) (E.Ramirez-Ruiz, private communication).

Alternative Angular Momentum Prescription In addition to the standard prescription for common envelope evolution based on comparing the binding and orbital energies (see above), we investigate the alternative approach proposed by Nelemans & Tout (2005), based on the non-conservative mass transfer analysis by Paczynski & Ziolkowski (1967), with the assumption that the mass loss reduces the angular momentum in a linear way. This leads
to reduction of the orbital separation

\[ \frac{\Delta a_{\text{in}}}{\Delta a_{\text{int}}} = \left( 1 - \gamma \frac{M_{\text{don,env}}}{M_{\text{tot, int}}} \right) \frac{M_{\text{tot, fin}}}{M_{\text{tot, int}}} \left( \frac{M_{\text{don, int}} M_{\text{acc, int}}}{M_{\text{don, fin}} M_{\text{acc, fin}}} \right)^2 \]  

(54)

where \( M_{\text{don, env}} \) is the mass of the donor envelope lost by the system, \( M_{\text{tot, int}}, M_{\text{tot, fin}} \) are the total masses of the system before and after CE, and \( \gamma \) is a scaling factor. Following Nelemans & Tout (2005) we use \( \gamma = 1.5 \) and note that hyper-critical accretion is not included in this prescription.

The two above prescriptions are extended (e.g., BKB02) to the case where both stars lose their envelopes, which happens if the stars have giant-like structure (\( K_i = 2,3,4,5,6,8,9 \)) at the onset of CE phases (see Bethe & Brown 1998).

5.5. Mass Transfer from Degenerate Donors

Degenerate donors (\( K_{\text{don}} = 10,11,12,16,17 \)), are also considered. The RLOF is assumed to be driven by gravitational radiation only

\[ M_{\text{don}} = M_{\text{don}} D^{-1} \frac{dJ_{\text{orb}}}{dt} \]  

(55)

with

\[ D = \frac{5}{6} \left( \frac{1}{2 \zeta_{\text{don}}} - \frac{1 - f_s}{3(1 + q)} (1 - f_s)(1 + q) \beta_{\text{int}} + f_s \right) q \]  

(56)

where the mass ratio is defined as \( q = M_{\text{acc}} / M_{\text{don}} \), \( f_s \) denotes the fraction of transferred mass that is accreted by the companion (defined and evaluated in §3.4), and \( \beta_{\text{int}} = M_{\text{don}}^2 / (M_{\text{don}} + M_{\text{acc}}) \).

5.6. Effects of Mass Transfer on Stellar Evolution

Mass loss/gain change the subsequent evolution of stars. We implement RLOF mass loss/gain by adding an extra term in the original Hurley et al. (2000) stellar evolution formulas. In case of mass loss we increase the wind mass loss rate to match the combined effects of wind and RLOF mass loss. To treat mass gain and potential accretor rejuvenation, we simply add the RLOF mass accretion rate, as calculated in §5.6, to the accretor wind mass loss rate (they have opposite signs), and calculate the net effect on the star. In most cases the accretor is gaining mass in RLOF (i.e., RLOF mass accretion rate is higher than wind mass loss rate). In this way we ensure that the subsequent evolution of the donor is followed consistently, i.e., evolutionary timescales and physical properties of mass losing/gaining stars are changed in agreement with stellar models. Our wind mass loss formulas are implemented the same way as in original Hurley et al. (2000, see their §7.1) and the above scheme allows for appropriate change of evolutionary timescales, both in case of mass loss and gain (Hurley 2003, private communication).

For simplicity, we assume that the composition of the accreted material matches that of the accretor, although this may not always be the case. Only in the case of accretion onto white dwarfs we take into account the composition of accreted material (see §5.7).

5.7. Mass Accumulation onto White Dwarfs

A number of important phenomena, e.g., novae and Type Ia SN explosions or accretion-induced collapses, are associated with mass accretion onto WDs. We incorporate the most recent results to estimate the accumulation efficiencies on WDs. In particular we consider accretion of matter of various compositions onto different WD types. We also include the possibility that NS formation can occur via accretion induced collapse (AIC) of a massive ONe white dwarf (e.g., Bailyn & Grindlay 1990; Belczynski & Taam 2004a).

In this section we discuss the accumulation of material and growth of the WD mass in binary systems. Only during dynamically stable RLOF phases can the mass accretion onto WDs be sustained for a prolonged period of time and hence affect the evolution of accreting WDs. During dynamically unstable cases (i.e., CE evolution) we assume that the WDs do not accrete any material.

If dynamical instability is encountered for a binary with two white dwarfs we assume that a merger occurs. Mergers of ONe with any type of WD companion and two CO WDs lead to either AIC and NS formation (if total merger mass \( M_{\text{merger}} \) is above \( M_{\text{ref}} = 1.38 M_\odot \)) or the formation of the single ONe WD (with new mass equal to \( M_{\text{merger}} \)). For mergers of CO WD and He WD, we assume a Type Ia SN explosion; either sub-Chandrasekhar (\( M_{\text{merger}} < 1.44 M_\odot \)) or Chandrasekhar mass SN Ia (\( M_{\text{merger}} > 1.44 M_\odot \)). Mergers of other types of WDs have total mass below the Chandrasekhar mass, and in particular for CO WD and H WD we assume formation of single CO WD, while for He WD and H WD we assume formation of single He WD with masses equal to \( M_{\text{merger}} \).

During a phase of sustained mass accumulation the massive ONe WD (\( K = 12 \)) may eventually collapse to a NS. We include AIC in our standard model calculations since it naturally follows from the adopted accumulation physics (see below). Since little is known about potential asymmetries of the collapse, we either apply no natal kick (standard model) or a full natal kick (parameter studies) obtained from Arzoumanian, Chernoff, & Cordes (2002) or Hobbs et al. (2005, see also §6.2). However, we also allow for the possibility of SN Ia explosion instead of AIC in parameter studies. It is also worth noting the difference between accretion and accumulation. The calculation of accretion rate during stable RLOF was described in §5.1, and this rate could be used to calculate, for example, the accretion luminosity of the system (mostly in the UV part of spectrum for WD accretors). However, it is believed that in many cases (see below) not all of the accreted material remains on the surface of the accreting WD. Mass is lost either in shell flashes (nova-like explosions) or through optically thick winds from the surface of accreting WDs. To calculate the actual WD mass growth through the RLOF phase the accumulation efficiency, \( \eta_{\text{acu}} \), which is defined as

\[ M_{\text{acu}} = \eta_{\text{acu}} M_{\text{acc}} \]  

(57)

must be known. Here, \( M_{\text{acu}} \) is the mass accumulation rate on the surface of WD and the mass accretion rate (\( M_{\text{acc}} \)) is given by eq. (19). In what follows we discuss the accumulation efficiency in various evolutionary scenarios.

Accretion onto Helium and Hybrid white dwarfs. It is
assumed that if the mass accretion rate $\dot{M}_{\text{acc}}$ from the H-rich donor ($K_{\text{don}} = 0, 1, 2, 3, 4, 5, 6, 16$) is smaller than some critical value $\dot{M}_{\text{crit1}}$, an unstable hydrogen shell flash will occur in the accreted layer. In response, the envelope will expand beyond the Roche lobe of the white dwarf. We shall assume no material is accumulated, and the accumulation efficiency is $\eta_{\text{acc}} = 0.0$, i.e., the entire accreted material is lost from the binary. If $\dot{M}_{\text{acc}} > \dot{M}_{\text{crit1}}$, then the material piles up on the WD leading to mass loss from the system and eventual inspiral. For giant-like donors we assume the system evolves through CE to examine if the system survives; for all other donors we call it a merger and halt binary evolution. The critical accretion rate is calculated as

$$\dot{M}_{\text{crit1}} = l_0 M_{\text{acc}}^2 (X \ast Q)^{-1} M_\odot \text{ yr}^{-1}$$  \hspace{1cm} (58)

where, $Q = 6 \times 10^{18} \text{ erg g}^{-1}$ is an energy yield of hydrogen burning, $X$ is the hydrogen content of accreted material. For Population I stars (metallicity $Z > 0.01$) we use $X = 0.7, l_0 = 1995262.3, \lambda = 8$, while for Population II stars ($Z \leq 0.01$) we use $X = 0.8, l_0 = 316228.8, \lambda = 5$ (Ritter 1999, see his eq. 10.12 and Table 2).

If the mass accretion rate from the He-rich donor ($K_{\text{don}} = 7, 8, 9, 10, 17$) is higher than $\dot{M}_{\text{crit2}} = 2 \times 10^{-8} M_\odot \text{ yr}^{-1}$ all the material is accumulated ($\eta_{\text{acc}} = 1.0$) until the accreted layer of material ignites in a helium shell flash. At this point degeneracy is lifted, a main sequence helium star ($K_{\text{acc}} = 7$) is formed and further accretion on the helium star is then taken into account. Following the calculations of Saio & Nomoto (1998) we estimate the maximum mass of the accreted shell at which the flash occurs as

$$\Delta M = \begin{cases} -7.8 \times 10^4 \dot{M}_{\text{acc}} + 0.13 \dot{M}_{\text{acc}} < 1.64 \times 10^{-6} \\ 0 \text{ (instantaneous flash)} \dot{M}_{\text{acc}} \geq 1.64 \times 10^{-6} \end{cases}$$  \hspace{1cm} (59)

where $\dot{M}_{\text{acc}}$ is expressed in $M_\odot \text{ yr}^{-1}$.

The newly formed helium star may overfill its Roche lobe, in which case either a single helium star is formed (He or Hyb WD companion, $K_{\text{don}} = 10, 17$), a helium contact binary is formed (HeMS companion, $K_{\text{don}} = 7$) which we assume leads to a merger or the system goes through CE evolution (evolved helium star companion, $K_{\text{don}} = 8, 9$).

For accretion rates lower than $\dot{M}_{\text{crit2}}$, accumulation is also fully efficient ($\eta_{\text{acc}} = 1.0$). However, the SN Ia occurs at a sub-Chandrasekhar mass

$$M_{\text{SNIa}} = -4 \times 10^6 \dot{M}_{\text{acc}} + 1.34 M_\odot,$$  \hspace{1cm} (60)

where $\dot{M}_{\text{acc}}$ is expressed in $M_\odot \text{ yr}^{-1}$. For mass accretion rates close to $\dot{M}_{\text{crit2}}$, the above extrapolations from the results of Hashimoto et al. (1986) yield masses smaller than the current mass of the accretor, and we assume an instantaneous SN Ia explosion. We note that above explosions disrupt the accreting WD, and although possibly subluminous, they appear as Type Ia SNe (no Hydrogen). We do not consider the accumulation of heavier elements since they could only originate from more massive WDs (e.g., CO or ONe WDs), which would have smaller radii and could not be donors to lighter He or Hyb WDs.

**Accretion onto Carbon/Oxygen white dwarfs.** In this case we adopt the prescription from Ivanova & Taam (2004). For H-rich donors and mass accretion rates lower than $10^{-11} M_\odot \text{ yr}^{-1}$ there are strong nova explosions and no material is accumulated ($\eta_{\text{acc}} = 0.0$). In the range $10^{-11} < \dot{M}_{\text{acc}} < 10^{-6} M_\odot \text{ yr}^{-1}$ we interpolate for $\eta_{\text{acc}}$ from Prinja & Kovetz (1995, see their Table 1). For rates higher than $10^{-6} M_\odot \text{ yr}^{-1}$ all accreted material burns into helium ($\eta_{\text{acc}} = 1.0$). Additionally we account for the effects of strong optically thick winds (Hachisu, Kato & Nomoto 1999), which eject any material accreted over the critical rate

$$\dot{M}_{\text{crit3}} = 0.75 \times 10^{-6} (\dot{M}_{\text{acc}} - 0.4) M_\odot \text{ yr}^{-1}. \hspace{1cm} (61)$$

This corresponds to $\eta_{\text{acc}} = \dot{M}_{\text{crit3}}/\dot{M}_{\text{acc}}$ for $\dot{M}_{\text{acc}} \geq \dot{M}_{\text{crit3}}$. The accretor is allowed to increase in mass up to $1.4 M_\odot$, and then explodes as a Chandrasekhar mass SN Ia. In the case of He-rich donors, if the mass accretion rate is higher than $\dot{M}_{\text{crit4}}$ helium burning is stable and contributes to the accretor mass ($\eta_{\text{acc}} = 1.0$). For rates in the range $\dot{M}_{\text{crit4}} < \dot{M}_{\text{crit3}}$ accumulation is calculated from

$$\eta_{\text{acc}} = -0.35 (\log \dot{M}_{\text{acc}} + 6.1)^2 + 1.02 \left[-6.5 \div -6.34\right]$$

$$\eta_{\text{acc}} = -0.35 (\log \dot{M}_{\text{acc}} + 5.6)^2 + 1.07 \left[-6.88 \div -6.05\right]$$

$$\eta_{\text{acc}} = -0.35 (\log \dot{M}_{\text{acc}} + 5.6)^2 + 1.01 \left[-6.92 \div -5.93\right]$$

$$\eta_{\text{acc}} = 0.54 (\log \dot{M}_{\text{acc}} + 4.16 \left[-7.06 \div -5.95\right]$$

$$\eta_{\text{acc}} = -0.54 (\log \dot{M}_{\text{acc}} + 5.6)^2 + 1.01 \left[-5.95 \div -5.76\right]$$

$$\eta_{\text{acc}} = -0.175 (\log \dot{M}_{\text{acc}} + 5.35)^2 + 1.03 \left[-7.35 \div -5.83\right]$$

$$\eta_{\text{acc}} = -0.115 (\log \dot{M}_{\text{acc}} + 5.7)^2 + 1.01 \left[-7.4 \div -6.05\right] \hspace{1cm} (62)$$

and represents the amount of material that is left on the surface of the accreting WD of a specific mass (denoted by a superscript on $\eta_{\text{acc}}$ in $M_\odot$) after the helium shell flash cycle (Kato & Hachisu 1999, 2004). Logarithms of critical mass accretion rates for a given specific WD mass are given in square brackets: $[\log (\dot{M}_{\text{crit4}}/ M_\odot \text{ yr}^{-1}) + \log (\dot{M}_{\text{crit4}}/ M_\odot \text{ yr}^{-1})]$. To obtain the accumulation rate for CO WD within the mass range $0.7 \div 1.4 M_\odot$ we incorporate results of the closest (by mass) model from the set of eqs. (62) If the WD mass drops below $0.7 M_\odot$ we use $\eta_{\text{acc}} = 1.0$ and we set $\log \dot{M}_{\text{acc}} = \log \dot{M}_{\text{crit4}} = -7.6$ (see Kato & Hachisu 2004). The mass of the CO WD accretor is allowed to increase up to $1.4 M_\odot$, and then a Chandrasekhar mass SN Ia takes place in the two above He-rich accretion regimes. If mass accretion rates drop below $\dot{M}_{\text{crit5}}$, the helium accumulates ($\eta_{\text{acc}} = 1.0$) on top of the CO WD and once the accumulated mass reaches $0.1 M_\odot$ (Kato & Hachisu 1999), a detonation follows and ignites the CO core leading to the disruption of the accretor in a sub-Chandrasekhar mass SN Ia (e.g., Taam 1980; Garcia-Senz, Bravo & Woosley 1999). If the mass of the accreting WD has reached $1.4 M_\odot$ before the accretion layer has reached $0.1 M_\odot$ then the accretor explodes in a Chandrasekhar mass SN Ia. Carbon/Oxygen accumulation takes place without mass loss ($\eta_{\text{acc}} = 1.0$) and leads to SN Ia if Chandrasekhar mass is reached.

**Accretion onto Oxygen/Neon/Magnesium white dwarf.** Accumulation onto ONe WDs is treated the same way as for CO WD accretors. The only difference arises when an
accretor reaches the Chandrasekhar mass. In the case of ONe WD this leads to an AIC and NS formation, and binary evolution continues (see Belczynski & Taam 2004a, 2004b).

6. SPATIAL VELOCITIES

6.1. Overview

All stars (single and binary systems) may be initialized with arbitrary velocities appropriate for a given environment. For example, a galactic rotation curve may be used for a field population of a given galaxy, or a velocity dispersion can be applied for a cluster population. The velocities of stars are then followed throughout their evolution. Single stars and binary systems are subject to recoil (change of spatial velocity) in SN explosions. Additionally, binary systems may be disrupted as a result of an especially violent explosion. We account for both mass/angular momentum losses as well as for SN asymmetries (through natal kicks that NSs and BHs receive at their formation; see below). The detailed description of SN explosion treatment is given in BKB02. Here, we only list the new additions to StarTrack. The most important modification allows us to trace velocities of disrupted binary components after a SN explosion. For the first time, a full general approach with explosions taking place on orbits of arbitrary eccentricity (in contrast to circular orbits only) is applied to follow the trajectories of disrupted components. First population synthesis results are presented in Belczynski et al. (2006).

6.2. Natal Kick Distribution

At the time of birth, NSs and possibly BHs receive a natal kick, which is connected to asymmetries in SN explosions. We use the distributions inferred from observed velocities of radio pulsars. We have replaced the natal kick distribution used in BKB02 (Cordes & Chernoff 1998) with two more recent alternatives. One presented by Arzoumanian et al. (2002) is a bimodal distribution with a weighted sum of two Gaussians, one with \( z_\text{oumanian et al. (2002)} \) is a bimodal distribution with two more recent alternatives. One presented by Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

\[ V_{\text{kick}} = (1 - f_{\text{fb}})V \]  

where \( V \) is the kick magnitude drawn from either Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

\[ V_{\text{kick}} = (1 - f_{\text{fb}})V \]  

where \( V \) is the kick magnitude drawn from either Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

\[ V_{\text{kick}} = (1 - f_{\text{fb}})V \]  

where \( V \) is the kick magnitude drawn from either Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

\[ V_{\text{kick}} = (1 - f_{\text{fb}})V \]  

where \( V \) is the kick magnitude drawn from either Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

\[ V_{\text{kick}} = (1 - f_{\text{fb}})V \]  

where \( V \) is the kick magnitude drawn from either Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

\[ V_{\text{kick}} = (1 - f_{\text{fb}})V \]  

where \( V \) is the kick magnitude drawn from either Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

\[ V_{\text{kick}} = (1 - f_{\text{fb}})V \]  

where \( V \) is the kick magnitude drawn from either Arzoumanian et al. (2002) or Hobbs et al. (2005) distribution, and \( f_{\text{fb}} \) is a fallback parameter, i.e., the fraction (from 0 to 1) of the stellar envelope that falls back (see also §2.3.1). For the most massive BHs, formed silently (no SN explosion) in a direct collapse \( f_{\text{fb}} = 1 \) of a massive star to a BH, we assume that no natal kick is imparted. The adopted natal kick distribution and kick scaling for NSs and BHs can be readily changed for parameter studies (e.g., full BH kicks).

6.3. Supernova disruptions

Just prior to the SN explosion, the two components of the binary move with velocities \( \vec{v}^I_1 \) and \( \vec{v}^I_2 \), which, in the center of mass (CM) system of coordinates, denoted here with the superscript \( I \), satisfy

\[ M_{1,\text{int}}\vec{v}^I_1 + M_{2,\text{int}}\vec{v}^I_2 = 0 \]  

where \( M_I \) denotes the SN component and \( M_2 \) its companion. Subscripts \( \text{int} \), \( \text{fin} \) stand for initial and final values.

We make no assumptions about the orbit; it can have an arbitrary eccentricity, in contrast to the derivation by Tauris & Takens (1998), who assumed that the orbit is circular prior to the explosion. At the moment of a supernova explosion the orbital separation is \( r_0\vec{n} \). The exploding star loses its envelope, its mass becomes \( M_{1,\text{fin}} \) and receives a kick \( \vec{w} \), so now its velocity in the coordinate system \( I \) is

\[ \vec{v}^I_{1,\text{int}} = \vec{v}^I_1 + \vec{w} \]  

The secondary star may be affected by the expanding shell and may receive an additional velocity \( \vec{v}_{\text{imp}} \), however it has been shown (Kalogera 1996) that the effect of this velocity is small, unless the pre-supernova orbital separation is smaller than \( \sim 3 R_\odot \). We assume that the velocity of the companion is not affected by the impact of supernova ejecta. We also assume that the velocity of the shell is large and the shell leaves the system quickly, i.e. \( v_{\text{shell}} \gg r_0P \), where \( P \) is the orbital period of the system prior to the explosion.

In order to calculate the final velocity of the two stars we first transform the velocities to the CM system of the two post-SN stars. The velocity of this system, denoted as \( \vec{v}^I \), in relation to system \( I \) is

\[ \vec{v}^I_{\text{CM}} = \frac{M_{1,\text{fin}}\vec{v}^I_{1,\text{int}} + M_{2,\text{int}}\vec{v}^I_2}{M_{1,\text{fin}} + M_2} \]  

The relative velocity of the two stars in this system is

\[ \vec{v}^I = \vec{v}^I_1 - \vec{v}^I_2 + \vec{w} - \vec{v}_{\text{imp}} \]  

while the initial direction between the two stars remains the same as in the coordinate system \( I \), \( \vec{v}^I = \vec{n}^I \). In this

\[ \vec{v}^I_{\text{CM}} = \frac{M_{1,\text{fin}}\vec{v}^I_{1,\text{int}} + M_{2,\text{int}}\vec{v}^I_2}{M_{1,\text{fin}} + M_2} \]  

The relative velocity of the two stars in this system is

\[ \vec{v}^I = \vec{v}^I_1 - \vec{v}^I_2 + \vec{w} - \vec{v}_{\text{imp}} \]  

while the initial direction between the two stars remains the same as in the coordinate system \( I \), \( \vec{v}^I = \vec{n}^I \). In this
new system the relative motion of the stars is a hyperbola in the plane perpendicular to the angular momentum vector:
\[ \vec{J} = \mu r_0 \vec{v}^{III} \times \vec{n}^{III}, \]  
(68)
where \( \mu = M_{1,\text{fin}} M_2 / (M_{1,\text{fin}} + M_2) \) is the reduced mass of the system. It is convenient now to introduce a third coordinate system \( III \) in which the angular momentum \( \vec{J} \) lies along the \( z \)-axis. The transformation from \( II \) to \( III \) is a rotation \( \mathcal{R} \): \( v_1^{III} = \mathcal{R} v_1^{II}, v_2^{III} = \mathcal{R} v_2^{II} \). The orbit in \( III \) is described by
\[ r = \frac{p}{1 + \epsilon \cos \phi}, \]  
(69)
where
\[ p = \frac{J^2}{\alpha \mu} \quad \text{and} \quad \epsilon = \sqrt{1 + \frac{2EJ^2}{\alpha^2 \mu}}, \]  
(70)
with \( E = (v_1^{II})^2/2 - \alpha / |r_0| \) is the (positive) energy of the system, and \( \alpha = GM_{1,\text{fin}} M_2 \). The final velocity, at \( r \to \infty \), follows from energy conservation:
\[ |\vec{v}_\text{fin}^{III}| = \sqrt{\frac{2E}{\mu}}. \]  
(71)
In order to find the direction of the final velocity we note that conservation of angular momentum implies that at infinity (\( r \to \infty \)): the final relative \( \vec{v}_\text{fin}^{III} \) is parallel to the direction between the stars \( \vec{n}_\text{fin}^{III} \). The initial position of the two stars on the trajectory described by eq. (69) is
\[ \cos \varphi_\text{int} = \frac{1}{\epsilon} \left( \frac{p}{r_0 - 1} \right). \]  
(72)
The sign of the angle \( \varphi_\text{int} \) is negative if the two stars initially lie on the descending branch of the hyperbola \( \vec{v}_\text{fin}^{III} > 0 \) and positive if they are on the ascending one \( \vec{v}_\text{fin}^{III} < 0 \). In the first case, when the two stars are initially on the descending branch, we need to compare the distance of closest approach on the orbit \( r_\text{min} = p/(1 + \epsilon) \) with the radius of the companion star to examine whether the two stars collide instead of escaping to infinity.

We obtain the final position on the trajectory from
\[ \cos \varphi_\text{fin} = -\frac{1}{\epsilon}, \]  
(73)
and \( \varphi_\text{fin} > 0 \). Thus the final direction between the two stars at \( r = \infty \) is \( \vec{n}_\text{fin}^{III} = T(\varphi_\text{fin} - \varphi_\text{int}) \vec{n}^{III} \), where \( T(\phi) \) is the matrix of rotation around the \( z \)-axis, and their relative velocity is:
\[ \vec{v}_\text{fin}^{III} = \sqrt{\frac{2E}{\mu}} \vec{n}_\text{fin}^{III}. \]  
(74)
We now have to transform quantities from system \( III \) back to system \( I \) to obtain the final velocities of the two disrupted binary components in the initial (pre-SN) CM system:
\[ v_1^{I,\text{fin}} = \mathcal{R}^{-1} \left( -\frac{M_2 v_2^{III}}{M_{1,\text{fin}} + M_2} \right) + v_\text{CM}^{II}, \]  
(75)
\[ v_2^{I,\text{fin}} = \mathcal{R}^{-1} \left( \frac{M_{1,\text{fin}} v_1^{III}}{M_{1,\text{fin}} + M_2} \right) + v_\text{CM}^{II}. \]  
(76)

7. DISTRIBUTIONS OF INITIAL PARAMETERS

Each binary system is initialized by four parameters, which are assumed to be independent: the primary mass \( M_1 \) (the initially more massive component), the mass ratio \( q = M_2/M_1 \), where \( M_2 \) is the mass of the secondary, the semi-major axis \( a \) of the orbit, and the orbital eccentricity \( e \).

For both single stars and binary system primaries, we use the initial mass function adopted from Kroupa, Tout & Gilmore (1993) and Kroupa & Weidner (2003),
\[ \Psi(M_1) \propto \left\{ \begin{array}{ll}
M_1^{-1.3} & 0.08 \leq M_1 < 0.5 \, M_\odot \\
M_1^{-2.2} & 0.5 \leq M_1 < 1.0 \, M_\odot \\
M_1^{-2 - \alpha_{\text{inf}}} & 1.0 \leq M_1 < 150 \, M_\odot
\end{array} \right. \]  
(77)
where parameter \( \alpha_{\text{inf}} = 2.35 - 3.2 \), with our standard choice being 2.7 for field populations and 2.35 for cluster populations. Stars are generated within an initial mass range: \( M_{\text{min}} - M_{\text{max}} \), and the range is chosen accordingly based on the targeted stellar population. For example, NS studies would require evolution of single stars within range \( \sim 8 - 25 \, M_\odot \) while the formation of WDs would require an initial range \( \sim 0.08 - 8 \, M_\odot \). Binary evolution, due to mass transfer events (both mass accretion and mass loss) may significantly broaden any of the ranges mentioned above.

We assume a flat mass ratio distribution,
\[ \Phi(q) = 1 \]  
(78)
in the range \( q = 0 - 1 \) in agreement with recent observational results of Kobulnicky, Fryer & Kiminki (2006). However, it should be noted that massive binaries may form with components of comparable mass (Pinsonneault & Stanek 2006), and we will test this alternative mass ratio distribution in our parameter studies. Given the value of the primary mass and the mass ratio, we obtain the mass of the secondary \( M_2 = q M_1 \).

The distribution of initial binary separations is assumed to be flat in the logarithm (Abt 1983),
\[ \Gamma(\alpha) \propto \frac{1}{\alpha}, \]  
(79)
where \( \alpha \) ranges from a minimum value, such that the primary fills at most 50% of its Roche lobe at ZAMS, up to \( 10^5 \, R_\odot \).

Finally, we adopt the thermal-equilibrium eccentricity distribution for initial binaries,
\[ \Xi(e) = 2e, \]  
(80)
in the range \( e = 0 - 1 \) (e.g., Heggie 1975; Duquennoy & Mayor 1991).

8. CALIBRATIONS AND COMPARISONS

8.1. Mass Transfer Sequences

In the following subsections we present StarTrack mass transfer calculations and compare them to published and unpublished results based on the use of stellar evolution and mass transfer codes.
8.1.1. Case B Mass Transfer: MS+HG binary

We choose this RLOF sequence from Wellstein et al. (2001, their Model B) and start with a 16 M⊙ + 15 M⊙ ZAMS binary in a 8 day circular orbit. RLOF starts after the primary evolves off the MS. The system at the onset of RLOF ($t = 11.7$ Myr since ZAMS) is characterized by: $K_1 = 2$, $K_2 = 1$, $P_{\text{orb}} = 7^4.9$, $e = 0$, $M_1 = 15.6$ M⊙, $M_2 = 14.7$ M⊙, $R_1 = 20.0$ R⊙, and $R_2 = 11.8$ R⊙. The evolution of the system during the RLOF phase is shown in Figure 6.

The RLOF phase proceeds on the thermal timescale of the donor, which is rapidly expanding while crossing the Hertzsprung Gap. First, there is a phase characterized by very high mass transfer rates ($\sim 3 \times 10^{-3}$ M⊙ yr⁻¹), until the mass ratio is reversed and the donor becomes the less massive binary component. Shortly thereafter, the transfer rate slowly decreases ($\sim 10^{-3} - 10^{-4}$ M⊙ yr⁻¹). After the mass ratio reversal the orbit starts expanding instead of contracting in response to mass transfer. Our assumption is that part (50%) of the transferred material is accreted by the companion and the rest is lost from the binary (non-conservative evolution). RLOF terminates when the envelope of the donor is nearly exhausted and its radius contracts below the Roche lobe radius, thereby, causing the system to become detached. The primary loses most of its mass and becomes a main sequence helium star ($M_1 = 4.03$ M⊙, $K_1 = 2$), while the secondary gains mass and is rejuvenated ($M_2 = 20.47$ M⊙, $K_2 = 1$). The orbital period increases to reach $\sim 80$ days at the end of the RLOF phase. Both stars continue to evolve in a detached configuration. The massive secondary evolves off the main sequence and becomes a Hertzsprung Gap star ($K_2 = 1$), while the primary is still a small main sequence helium star. The rapidly expanding secondary overfills its Roche lobe and initiates the second mass transfer episode. This leads to a common envelope phase (due to the very high mass ratio of $\sim 20/4$), component inspiral and final merger of the two stars, terminating binary evolution.

The calculation of Wellstein et al. (2001) shows similar behavior during the first RLOF phase in terms of the duration, mass transfer rate, and orbital period. The final donor masses in both simulations are almost the same, while our accretor mass is significantly smaller than that of Wellstein et al. (2001). This difference stems from their assumption of conservative (no mass loss from binary) binary evolution. However, Wellstein et al. (2001) find a second RLOF phase, when the primary expands again, once it becomes a helium giant ($K_1 = 8 - 9$). Additionally, they find that at that time the secondary is still a main sequence star ($K_2 = 1$). Their system evolves through, so called, case BB mass transfer phase. The RLOF stops when the primary loses significant part of its Helium envelope. The system becomes wider, and eventually the primary explodes in type Ib/c supernova. The difference in the evolution into second RLOF is explained by the treatment of rejuvenation in both calculations. The secondary star in Wellstein et al. (2001) calculation is hardly rejuvenated, so although it has high mass ($M_2 = 26.7$ M⊙) after the first RLOF phase, it still evolves on a long timescale corresponding to the initial mass of secondary ($M_2 = 15$ M⊙). In contrast, in our calculation we adopt full rejuvenation, and our secondary evolves much faster, on the nuclear timescale relevant for a star of mass $M_2 = 20.47$ M⊙ (the mass of secondary after first RLOF). Therefore, in our calculation, the secondary fills its Roche lobe first, crossing the Hertzsprung Gap, while in Wellstein et al. (2001) the primary star initiates the second RLOF, leading to a quite different fate for the binary.

8.1.2. Case A Mass Transfer: MS+MS binary

This RLOF sequence is selected from Wellstein et al. (2001, their Model A). We start with a 12 M⊙ + 7.5 M⊙ ZAMS binary in a 2.5 day circular orbit. RLOF starts while the primary still evolves through the MS phase. The system at the onset of RLOF ($t = 14.8$ Myr since ZAMS) is characterized by: $K_1 = 1$, $K_2 = 1$, $P_{\text{orb}} = 2^3.3$, $e = 0$, $M_1 = 11.9$ M⊙, $M_2 = 7.5$ M⊙, $R_1 = 8.3$ R⊙, and $R_2 = 4.0$ R⊙. The evolution of the system during the RLOF phase is shown in Figure 6. In this calculation we invoke conservative evolution ($f_a = 1.0$; all mass lost from donor is accreted by the companion) to match the assumption in Wellstein et al. (2001).

First phase. At first, the RLOF proceeds on the thermal timescale with a mass transfer rate of $\sim 5 \times 10^{-4}$ M⊙ yr⁻¹, through the so called rapid case A transfer phase. The transfer rate then rapidly decreases by more than 2 orders of magnitude until the component masses are nearly equal. Subsequent evolution proceeds on the much slower nuclear timescale of the donor with transfer rates below $10^{-6}$ M⊙ yr⁻¹. RLOF continues until the final stages of the donor MS lifetime, when the primary contracts and detaches from its Roche lobe. The evolution of the orbital period is characterized by an initial small decrease and then (after the thermal timescale phase has ended) a slow but rather constant increase up to 3.2 days. At that point the primary mass is $\sim 6$ M⊙ and the secondary mass $\sim 13$ M⊙.

Second phase. After $\sim 0.2$ Myr the primary starts expanding as it enters the Hertzsprung Gap and RLOF restarts. This mass transfer phase is much more rapid and is driven by expansion of the primary. This phase is characterized by high mass transfer rate ($10^{-4} - 10^{-6}$ M⊙ yr⁻¹) and the envelope of the primary is soon ($\sim 1$ Myr) exhausted, ending the second RLOF phase. During this relatively short phase, the orbit expands significantly (final orbital period $\sim 270$ days), while the primary loses most of its mass ($M_1 \approx 1$ M⊙) while the secondary, still on its MS, gains mass ($M_2 \approx 18$ M⊙) and is rejuvenated. The dramatic orbit expansion is an effect of the rather extreme mass ratio for this system at the time of the second RLOF. For both RLOF phases conservative evolution was applied. The evolution of this system ends when the massive secondary evolves off MS, initiating a CE phase while crossing the Hertzsprung Gap. This phase leads to inspiral and merger.

The calculation of Wellstein et al. (2001) shows a qualitatively similar system behavior during both RLOF phases; initial high mass transfer phase, then a slower one, short break in RLOF followed by another rapid phase while the donor evolves off the MS. However, there is a significant difference in the duration of both RLOF phases, our calculation showing factor of $\sim 3$ longer RLOF phases than these of Wellstein et al. (2001). As our donor loses mass, its evolution slows down (opposite of rejuvenation) which makes the RLOF phase last longer. Also, the mod-
els of the stripped (through RLOF) stars must differ in both calculations leading to the different mass transfer timescales. The period of our system after second RLOF is much longer (270 days) than \(~10^2\) days found by Wellstein et al. (2001). That difference must come from the fact that we include spin-orbit coupling in our calculations, while it is neglected by Wellstein et al. (2001).

Wellstein et al. (2001) remark that had full rejuvenation been included in their calculation the system would have ended in a CE merger during the expansion phase of the secondary after MS evolution in agreement with our findings.

8.1.3. BH-MS binary

This calculation starts with a 10 M\(_\odot\) BH + 5 M\(_\odot\) ZAMS star. We let the secondary evolve through about half of its MS lifetime before bringing the system into contact at \(t = 51.3\) Myr (counted from the secondary ZAMS). The system at the onset of RLOF is characterized by: \(K_1 = 14, K_2 = 1, P_{\text{orb}} = 1^{4.0}, e = 0, M_1 = 10 M_\odot, M_2 = 5 M_\odot, R_1 = 0.000042 R_\odot\), and \(R_2 = 3.5 R_\odot\). The evolution of the system during the RLOF phase is shown in Figure 7.

First phase. RLOF is stable and proceeds on the nuclear timescale of the secondary with a mass transfer rate of \(\sim 2 \times 10^{-8} M_\odot\) yr\(^{-1}\). Since this rate is sub-Eddington we allow all the transferred material to be accreted onto the primary BH, which increases its mass to \(\sim 11.5 M_\odot\), while the secondary mass decreases to \(\sim 3.5 M_\odot\). During this phase, the period increases from 1 to 2 days. The phase ends when the secondary begins contraction at the end of its MS life.

Second phase. RLOF restarts when the secondary crosses the Hertzsprung Gap with mass transfer proceeding at the high rate (\(\sim 10^{-6} M_\odot\) yr\(^{-1}\)) corresponding to rapid expansion of the star on its thermal timescale during that phase. At some point the donor starts ascending along the red giant branch, and the transfer rate drops by about an order of magnitude to \(\sim 3 \times 10^{-7} M_\odot\) yr\(^{-1}\). Since the transfer rate is super-Eddington throughout this entire phase we limit accretion onto the BH to the Eddington rate, allowing the rest of the material to leave the binary with the specific orbital angular momentum of the BH. In the end the BH has increased its mass to 12.6 M\(_\odot\) and the mass of the donor has decreased to 0.6 M\(_\odot\). The orbit expands significantly (\(\sim 300\) days) during this rapid RLOF phase.

The RLOF phase ends at the point when the donor, due to the loss of its almost entire H-rich envelope, stops its expansion. The system ends its life as a wide BH-WD binary.

The same RLOF sequence was calculated with the detailed stellar evolution code of Ivanova et al. (2003; also see Ivanova & Taam 2004). The comparison of the two phases of RLOF shows overall qualitative agreement with the StarTrack calculation. The mass transfer rates are virtually the same: \(\sim 2 \times 10^{-8}\) and \(\sim 10^{-6} M_\odot\) yr\(^{-1}\), for first and second phase, respectively. However, the detailed calculation with the evolution code shows a longer duration (by a factor \(~2\)) for the first RLOF phase.

8.1.4. BH-RG binary

This calculation starts with a 7 M\(_\odot\) BH + 2 M\(_\odot\) ZAMS star. We let the secondary evolve through about one third of its red giant lifetime before bringing the system into contact at \(t = 1180.4\) Myr (counted from the secondary ZAMS). The system at the onset of RLOF is characterized by: \(K_1 = 14, K_2 = 3, P_{\text{orb}} = 4^{5.8}, e = 0, M_1 = 7 M_\odot, M_2 = 2 M_\odot, R_1 = 0.000030 R_\odot\), and \(R_2 = 7.1 R_\odot\). The evolution of the system during RLOF phase is shown in Figure 8.

RLOF is stable and proceeds through the entire RG phase (\(K_2 = 3\)) on the nuclear timescale of the donor. The mass transfer rate is sub-Eddington and thus the material transferred to the BH is entirely accreted. In the end the mass of the BH is increased to 8.4 M\(_\odot\) while the mass of the donor is decreased to 0.6 M\(_\odot\). As the donor expands, ascending the RG branch, the orbit expands as well, and finally the RLOF phase terminates at an orbital period of \(~90\) days. The phase ends when the donor contracts upon igniting helium in its core. The system eventually forms a wide BH-WD binary.

This RLOF sequence was also calculated with the detailed stellar evolution code of Ivanova et al. (2003). The mass transfer rates found in both cases are similar (\(~10^{-7} - 10^{-8} M_\odot\) yr\(^{-1}\)) and in this case the StarTrack timescales are shorter, but do not differ by more than 50%.

8.1.5. Short period NS-RG binary

This RLOF sequence is chosen from Tauris & Savonije (1999, their example 2b). We start with a 1.3 M\(_\odot\) NS + 1.6 M\(_\odot\) ZAMS star in a 3 day circular orbit. RLOF starts while the secondary is on the RG branch (\(t = 2321.4\) Myr since secondary ZAMS) and the binary is described by: \(K_1 = 13, K_2 = 3, P_{\text{orb}} = 2^{4.8}, e = 0, M_1 = 1.3 M_\odot, M_2 = 1.6 M_\odot, R_1 = 0.00014 R_\odot\), and \(R_2 = 4.7 R_\odot\). The evolution of the system during the RLOF phase is shown in Figure 8.

At first the RLOF proceeds on a thermal timescale with a highly super-Eddington mass transfer rate (\(\sim 10^{-6} M_\odot\) yr\(^{-1}\)). After the donor becomes less massive than its accretor, the mass transfer is driven by the expansion of the red giant donor (on its nuclear timescale) at a much smaller rate of \(\sim 10^{-8} M_\odot\) yr\(^{-1}\). As the mass transfer rate decreases, the NS starts to accrete efficiently and its mass increases to 1.9 M\(_\odot\). Eventually, after \(~65\) Myr of RLOF, the RG secondary loses most of its mass (\(M_2 = 0.28 M_\odot\)) and contracts, leaving a remnant helium WD. At this point the RLOF phase ends (orbital period 60 days), and further evolution leads to the formation of wide binary, with a recycled pulsar.

Comparison with the detailed evolutionary calculation of Tauris & Savonije (1999) shows good agreement between the results. The detailed calculations show an initial rapid RLOF phase followed by a sub-Eddington mass transfer phase, eventually leading to the formation of NS-He WD binary. Final component masses (NS and donor: 2.05 and 0.29 M\(_\odot\), respectively) are very similar to the ones obtained with StarTrack. The final orbital period of 42 days obtained by Tauris & Savonije (1999) is shorter than in our calculation (60 days). In addition, there is a difference in the duration of RLOF phase, lasting 123 Myr in the Tauris & Savonije (1999) model, as compared to 60 Myr in our calculations. This may be understood in terms of a different treatment of binary interactions (tides,
magnetic braking, winds) as well as the difference in stellar models which may lead to a different starting point of RLOF.

8.1.6. Long period NS-RG binary

This RLOF sequence is taken from Tauris & Savonije (1999, their example 2c). We start with a 1.3 M\odot NS + 1.0 M\odot ZAMS star in a 60 day circular orbit. RLOF starts while the secondary is on the RG branch (t = 12312.5 Myr since secondary ZAMS) and the binary is described by: \( K_1 = 13, K_2 = 3, P_{\text{orb}} = 60^{\circ}.708033, e = 0, M_1 = 1.3 M\odot, M_2 = 0.98 M\odot, R_1 = 0.000014 R\odot, \) and \( R_2 = 30.5 R\odot. \) The evolution of the system during RLOF phase is shown in Figure 11.

RLOF is highly super-Eddington and driven by the expansion of the donor on a nuclear timescale. Only shortly before the system detaches as a result of the exhaustion of the donor’s envelope, the transfer rate becomes sub-Eddington. As a result, the donor loses most of its mass \( (M_2 = 0.4 M\odot) \) while the NS hardly accretes any material \( (M_1 = 1.43 M\odot). \) The orbit expands throughout this phase with the orbital period increasing to over 300 days. The system eventually forms a wide NS-He WD binary, with a potential recycled pulsar (the NS has accreted \( \sim 0.1 M\odot). \)

The above results are very similar to the calculations of Tauris & Savonije (1999), who obtain a 1.5 M\odot NS with a 0.4 M\odot NS-He WD binary in a 382 day orbit. The mass transfer rates and duration of the RLOF phases are similar in both calculations.

8.1.7. Long period NS-He star binary

This RLOF sequence follows from Dewi & Pols (2003, see their Fig. 1). We start with a 1.4 M\odot NS + 2.8 M\odot ZAMS He star in a 10 day circular orbit. RLOF starts while the secondary is already an evolved He star \( (t = 2.9 \text{ Myr}) \) and the binary is described by: \( K_1 = 13, K_2 = 8, P_{\text{orb}} = 9^{\circ}.804617, e = 0, M_1 = 1.4 M\odot, M_2 = 2.5 M\odot, R_1 = 0.000014 R\odot, \) and \( R_2 = 15.4 R\odot. \) The evolution of the system during RLOF phase is shown in Figure 11.

RLOF proceeds on the donor’s thermal timescale throughout the entire phase. The very high mass transfer rate \( (6 \times 10^{-3} M\odot \text{ yr}^{-1}) \) makes this phase very short and RLOF stops after the envelope of He star is exhausted. Since the mass transfer rate is highly super-Eddington, the NS hardly accretes any material while the donor loses its entire He-rich envelope \( (M_2 = 1.65 M\odot). \) The orbital period at first decreases to a minimum at 8.9 days, and then increases to 9.5 days at the end of RLOF phase.

After the phase of RLOF the secondary core explodes in SN Ic leading to double neutron star formation (provided that a natal kick does not disrupt the binary). This result was presented also in Ivanova et al. (2003).

Dewi & Pols (2003) calculated mass transfer rates spanning the range: \( 10^{-4} - 10^{-2} M\odot \text{ yr}^{-1}. \) Our rate is constant and close to the high end of the Dewi & Pols (2003) range. We have adopted a constant mass transfer rate following Paczynski (1971) who pointed out that thermal timescale mass transfer rates do not vary by more than factor of 2-3 (for details see § 5.3). This system may appear as an X-ray binary during this phase. However, the chances of catching it at this phase are very small, since the thermal timescale mass transfer is very short. Besides, in this case the X-rays may be significantly degraded because of high optical depths (material shed out of the system). On the other hand, some of these sources might appear to be soft \( \gamma - \text{ray} \) emitters (i.e. \( 20 - 100 \text{ keV} \) range, tail of X-ray emission) with high intrinsic absorption, and the discovery of objects with these broad characteristics (see e.g., Dean et al. 2005) lends some hope for detecting this phase of binary evolution. The results from Dewi & Pols (2003) reveal a different period evolution than in our simulation; RLOF starts at higher value \( (10.46 \text{ days}) \), and then decreases to 10.37 days. However, the period changes in both calculations are rather small, and are probably related to our consistently high mass transfer rate throughout the RLOF phase. This leads to higher mass and angular momentum loss from the binary which determines the orbit evolution. Additionally, we include tidal interactions between binary components (see § 3.3 and § 8.2). These differences between models for low mass helium stars were already noted by Dewi & Pols (2003).

8.1.8. Short period NS-He star binary

We choose this RLOF sequence from Dewi & Pols (2003, see their Fig. 3). We start with a 1.4 M\odot NS + 3.6 M\odot ZAMS He star in a 0.6 day circular orbit. RLOF starts while the secondary is already an evolved He star \( (t = 2.0 \text{ Myr}) \) and the binary is described by: \( K_1 = 13, K_2 = 8, P_{\text{orb}} = 0^{\circ}.59, e = 0, M_1 = 1.4 M\odot, M_2 = 3.2 M\odot, R_1 = 0.000014 R\odot, \) and \( R_2 = 2.4 R\odot. \) The evolution of the system during RLOF phase is shown in Figure 12.

The RLOF proceeds on the donor’s thermal timescale with a mass transfer rate of \( \sim 10^{-3} M\odot \text{ yr}^{-1} \) until the envelope of He star is almost exhausted. Since the mass transfer rate is highly super-Eddington, the NS does not accrete much material while the donor loses most of its He-rich envelope \( (M_2 = 2 M\odot). \) The orbital period decreases from 0.6 to \( \sim 0.4 \) days at the end of RLOF phase. After the RLOF phase ceases the secondary explodes in SN Ib/Ic leading to a close double neutron star system (again provided that a natal kick does not disrupt the binary).

The Dewi & Pols (2003) RLOF sequence for this case is very similar to our calculation. They find a period decrease (from 0.65 to 0.47 days) and a high constant mass transfer rate of a few \( \times 10^{-4} M\odot \text{ yr}^{-1}. \) The inspiral phase and CE is not expected in this case, and therefore further evolution may lead to a close double neutron star formation.

8.2. Tidal Evolution Calibration

Whenever coeval binary populations in nearby clusters are observed to constrain the circularization rate, it is found that standard tidal dissipation theories do not match the data (see Meibom & Mathieu 2005 for a recent review). In all cases an increase in the tidal dissipation rate appears necessary (Claret & Cunha 1997; Terquem et al. 1998). Depending on which theory is used, the increase needed in the overall efficiency of tidal dissipation is by a factor \( \sim 10 - 100. \)

We have used StarTrack models to calibrate our theoretical treatment by comparing them against observations.
of (i) the cutoff period for circularization in a population of MS binaries (in M67), and (ii) the orbital decay accompanying tidal synchronization in a high mass X-ray binary (LMC X-4). The results, presented in two following subsections, confirm that tidal dissipation, at least in case of convective stars, is more effective than predicted by our simple theory. Therefore, in all our standard model calculations, we will use an increased rate of tidal dissipation for convective stars, corresponding to $F_{\text{tid,con}} = 50$, while using standard dissipation for radiative stars $F_{\text{tid,rad}} = 1$, but we will also allow for even more effective tidal dissipation rates in our parameter studies (all the way to $F_{\text{tid,con}} = 100$ and $F_{\text{tid,rad}} = 100$). See §3.3 for our implementation of tidal dissipation theory and the definition of $F_{\text{tid}}$.

8.2.1. Cutoff Period for M67

Open star clusters have often been used to test tidal interaction theories (Mathieu et al. 1992; Meibom & Mathieu 2005). Observations of single- and double-line spectroscopic binaries allow estimates of the periods and eccentricities for a number of systems within clusters. It was expected and then confirmed that the cutoff period ($P_{\text{cut}}$, the longest period of a circular binary) should increase with the age of the cluster. The tidal dissipation depends strongly on the orbital separation and therefore the wider, longer-period binaries will take a greater time to circularize. In principle, with knowledge of the initial conditions in a given cluster, the observed value of the cutoff period may be used to calibrate the efficiency of tidal interactions. In practice, binaries within a given cluster form with eccentricities, separations and angular momenta which are not precisely known. In addition, the observed samples may suffer from small number statistics (the observed cutoff periods are only lower limits), rendering such a calibration quite uncertain. However, we can use the cutoff-period observations to provide at least an order of magnitude estimate for the factor by which any standard theoretical estimate must be increased.

M67 is an old open cluster with an age of 3.98 Gyr and observed cutoff period of $10 - 12$ d (Mathieu, Latham & Griffin 1990; Mathieu et al. 1992) and a solar metallicity stellar population (Janes & Phelps 1994). The period was estimated for a sample of MS binaries with components close to the cluster turnoff mass. Recently Meibom & Mathieu (2005) proposed a new way to estimate the point of transition from circular to eccentric systems. Instead of a simple cutoff period, they use a new estimator called the “tidal circularization period.” This period is found from fitting a special function which mimics the tidal circularization isochrone of the most frequently occurring eccentric binary orbits for a given cluster. They find that the tidal circularization period for M67 is $12.1$ d.

Several calculations, with different efficiencies of tidal dissipation, were performed to try to reproduce the binary population of the open cluster M67. In each calculation we have evolved $10^3$ binaries at solar metallicity with component masses in the $0.7 - 1.4 M_\odot$ range, requiring that the mass ratio be greater than $0.5$. The limits are somewhat arbitrary, but chosen to include the population of bright MS stars observed in M67. Most of these stars have convective envelopes, and therefore we try to calibrate the scaling factor for convective envelopes ($F_{\text{tid,con}}$) while keeping the one for radiative stars constant ($F_{\text{tid,rad}} = 1$). The initial distributions were chosen as in our standard evolutionary model (see §5.7), but with IMF exponent $\alpha_{\text{inf}} = 2.35$, which is more appropriate for clusters (Kroupa & Weidner 2003).

In Figure 13 we show synthetic binary MS populations in the period–eccentricity plane corresponding to an evolution with different efficiencies for the tidal interaction. As expected we see that the cutoff period increases for more efficient tidal interactions, $P_{\text{cut}} \approx 4, 7, 10$ d for $F_{\text{tid,con}} = 1.1, 10, 100$, respectively. It is found that only for significantly increased dissipation ($F_{\text{tid,con}} \gtrsim 10 - 100$) the the predicted cutoff period approach the observed value of 10-12 days. An additional calculation with $F_{\text{tid,con}} = 1000$ results in a cutoff period of $\sim 16$ days, now clearly higher than the observed value.

8.2.2. Orbital decay of LMC X-4

Levine, Rapaport & Zojcheski (2000) measured an orbital period decay for the high mass X-ray binary (HMXB) LMC X-4. The system consists of a 1.3 $M_\odot$ NS and a massive 15.6 $M_\odot$ companion in a 1.4-day circular or almost circular orbit (Woo et al. 1996; van der Meer et al. 2005). The X-ray emission in HMXBs is believed to arise from wind accretion onto the compact object; however it was also suggested that some systems may be in an atmospheric RLOF phase (e.g., Kaper 2001). For wind-fed detached systems, the orbital decay may be directly connected to the tidal interaction of the HMXB components. The secondary is a massive star, and the source of tidal dissipation is radiative damping. Therefore, we use LMC X-4 to check the efficiency of tidal interactions for radiative envelopes ($F_{\text{tid,rad}}$). The rotation of the massive component decreases with time as it expands during its evolution. On the other hand, the tidal forces act to synchronize the massive component, resulting in loss of orbital energy and angular momentum, i.e., decay of the orbit.

If, in fact, LMC X-4 is a wind-fed system and not in RLOF, then the massive star must be smaller than its Roche lobe $R_{\text{roche}} = 8 R_\odot$. A 15.6 $M_\odot$ star exceeds that size, while still on MS, after about 10.5 Myr of evolution (from the ZAMS). Subsequent RLOF is dynamically unstable (extreme mass ratio) and leads to a rapid merger of the binary components, terminating the HMXB phase. We perform a set of calculations for a synthetic binary similar to the LMC X-4 using our standard model parameters, with a metallicity appropriate for the LMC ($Z = 0.007$). We assume that the binary configuration is detached and we calculate the rate of orbital decay. The orbital decay rate depends crucially on the current relative radius of the massive component of LMC X-4 ($\propto (R/a)^8$, see eq. 17).

The radius of the 15.6 $M_\odot$ star ($Z = 0.007$) increases from $R_2 = 4.5 R_\odot$ on ZAMS to $R_2 = 13 R_\odot$ at the end of MS phase, which takes $\sim 13$ Myr. Based on the Roche lobe radius of secondary for 1.4 day orbit the secondary fills its Roche lobe at $\sim 11$ Myr, which is close to the end of MS phase. Since the primary has already evolved and has formed a NS, a significant amount of time must have elapsed since the binary formation. For example a 30 – 35 $M_\odot$ star takes $\sim 6$ Myr to form compact object, and such a massive star would have formed a NS only if stripped of a significant part of its mass in RLOF episode. For more massive primaries, the evolution would
be slightly faster (~4–5 Myr), but they would more likely have formed BHs. So on one hand the secondary cannot be older than ~11 Myr (R₂ = 8 R⊙ and R₂/R₂,lob = 1) and most likely it is not younger than ~6 Myr (R₂ = 6 R⊙ and R₂/R₂,lob = 0.75). We conclude that the secondary is in the late stage of its evolution on the main sequence and probably close to filling its Roche lobe (see also Levine et al. 2000).

We perform the set of calculations for different radii of the massive component of LMC X-4 (R₂/R₂,lob = 0.75 − 0.9) for various efficiencies of tidal interactions (F_{tid,rad} = 1,10). The results are shown in Figure 14. The orbital decay rate increases with time as the massive component expands along the MS and approaches its Roche lobe. The time to reach contact (at which point calculations are stopped) decreases with increasing effectiveness of tidal forces. For comparison we show the observed orbital decay for LMC X-4, which falls within the model with standard tidal interactions efficiency (F_{tid,rad} = 1). We conclude that in the case of LMC X-4 there is no need for the increased efficiency of tidal interactions, and therefore we adopt F_{tid,rad} = 1 for massive stars with radiative envelopes for our standard model value.

**9. X-RAY MODELING**

**9.1. X-ray luminosity calculations**

In our study we consider only accreting binaries with NS and BH primaries, which are brighter than some X-ray luminosity cut L_{x,cut}. This cut may correspond to a detection limit of a particular set of observations. Typical L_{x,cut} values for most current Chandra observations are in the range 10^{34} – 10^{36} erg s^{-1}. At these high luminosities in the Chandra sensitivity range (~0.3 – 7 keV) the only WD accretors will be supersoft sources, which are easily identifiable from their X-ray spectra and are thought to have most of their X-ray emission coming from nuclear burning rather than gravitational energy release (see Kuulkers et al. 2003 for a review of the X-ray properties of WD accretors). Although, for some deep Galactic exposures Chandra has reached levels of ~10^{30} erg s^{-1} (e.g., Galactic Center image of Muno et al. 2003) and a contribution from cataclysmic variables may also become important. The calculation of X-ray luminosities of systems with WD accretors is described in a separate study (Ruiter, Belczynski & Harrison 2006).

Binary companions to NS/BHs may lose material either through a stellar wind or via RLOF. In the latter case, the donors transfer all the material toward the accretor, whereas for the wind-fed systems only a fraction of the material is captured by the compact object. We calculate the bolometric luminosity (L_{bol}) arising from the accretion onto a compact object. The accretion rate is based on the secular averaged mass accretion rate. If a system is detached then we use the wind mass accretion rate (eq. [44]), and if system is semi-detached the RLOF accretion rate is used (eq. [45]). We do not calculate X-ray luminosities arising from the accretion in dynamically unstable phases, since the timescales are very short and additionally X-ray emission would be highly absorbed due to large optical depths in the CE. The L_{bol} is calculated from

\[ L_{bol} = \epsilon \frac{GM_{acc}M_{acc}}{R_{acc}} \]  

where the radius of the accretor is 10 km for a NS and 3 Schwarzschild radii for a BH, and \( \epsilon \) gives a conversion efficiency of gravitational binding energy to radiation associated with accretion onto a NS (surface accretion \( \epsilon = 1.0 \)) and onto a BH (disk accretion \( \epsilon = 0.5 \)).

For RLOF-fed systems we make a distinction between persistent and transient X-ray sources. All wind-fed systems are considered as persistent X-ray sources. The issue of the wind-fed XRBs with massive Be companions and their outburst behavior is discussed in §9.2.

RLOF-fed systems are subject to a thermal disk instability and may appear either as persistent or transient X-ray sources depending on the mass transfer rate. A system becomes a transient X-ray source when the RLOF rate falls below a certain critical value \( M_{disk} \). We use the work of Dubus et al. (1999) for H-rich disks (see their eq.30) and the study of Menou, Perna, & Hernquist (2002) for disks with heavier elements (see their eqs.1–4)

\[
\dot{M}_{disk} = \begin{cases} 
1.5 \times 10^{15} M_{acc}^{-0.4} R_{disk}^{2.1} C_{0.5}^{-0.5} \text{gs}^{-1} & \text{H - rich} \\
5.9 \times 10^{16} M_{acc}^{-0.87} R_{disk}^{2.62} C_{0.44}^{-0.44} \text{gs}^{-1} & \text{He - rich} \\
1.2 \times 10^{16} M_{acc}^{-0.74} R_{disk}^{2.21} C_{0.42}^{-0.42} \text{gs}^{-1} & \text{CO - rich} \\
5.0 \times 10^{16} M_{acc}^{-0.68} R_{disk}^{2.05} C_{0.45}^{-0.45} \text{gs}^{-1} & \text{O - rich},
\end{cases}
\]  

where \( M_{acc} \) is accretor mass in \( M_{\odot} \), \( R_{disk} \) is a maximum disk radius (2/3 of accretor Roche lobe radius) in \( 10^{10} \) cm. Constants are: \( C_{i} = C/(5 \times 10^{-4}) \), with C being radiation parameter of typical value \( 5 \times 10^{-4} \); \( \alpha_{0.1} = \alpha/0.1 \), with \( \alpha \) being a viscosity parameter. Following Menou et al. (1999) we adopt \( \alpha = 0.1 \) for all types of donors since there is empirical evidence from dwarf nova outbursts that this is the right order of magnitude for the viscosity parameter. The same value of \( \alpha \) is used to derive the critical mass transfer rate for H-rich disks (Dubus et al. 1999). H-rich donors are the stars with types \( K_{i} = 0,1,2,3,4,5,6,16 \), He-rich donors are \( K_{i} = 7,8,9,10,17 \), CO-rich donors are \( K_{i} = 11 \), while we apply formulas for O-rich type donors to ONe WDs (\( K_{i} = 12 \)).

We adopt a semi-empirical approach to calculate quiescent X-ray luminosities of transient NS RLOF-fed sources, since little is known about the emission mechanism during quiescence. It is not certain if the emission arises from a low level accretion or a deep crustal heating (for a detailed discussion see Belczynski & Taam 2004b, and references therein). Using X-ray studies of Galactic transient systems with NS accretors (e.g., Tavani & Arons 1997; Rutledge et al. 2001; Campana & Stella 2003; Jonker, Wijnands & van der Klis 2004; Tombick et al. 2004; Campana 2004), we adopt \( 10^{31} \text{erg s}^{-1} \) as a lower limit for the hard X-ray luminosity, above 2 keV. However, it was shown that the average luminosity level can be higher \( > 10^{32} \text{erg s}^{-1} \) (e.g., Rutledge et al. 2002; Jonker et al. 2004). We adopt an X-ray luminosity level of \( 10^{31} - 10^{32} \text{erg s}^{-1} \) above 2 keV. Furthermore, we assume that the quiescent NS transient is a maximum.
X-ray luminosities are evenly distributed (in log $L_x$) in the above range.

The quiescent emission from BH transient systems is likely related to a low level of mass accretion. Recent observations of BH transients in their quiescent states (Tomski et al. 2003) reveal rather hard spectra that are not well described by a black body. The observed luminosities are found in the range $\sim 10^{30} - 10^{33}$ erg s$^{-1}$ with a median luminosity $\approx 2 \times 10^{31}$ erg s$^{-1}$. For BH systems we also use a semi-empirical approach, and we assume that most (80%) of the quiescent BH transient X-ray luminosities above 2 keV are evenly distributed in the $10^{30} - 10^{32}$ erg s$^{-1}$ range, while the rest (20%) of the systems are slightly brighter: luminosities evenly distributed in the $10^{32} - 10^{33}$ erg s$^{-1}$ range (see Fig. 3 of Tomski et al. 2003). Both of the above distributions are uniform in log $L_x$. There are some indications that the highest quiescent luminosities are found in the longest period systems (e.g. Garcia et al. 2001), but we do not implement this effect until confirmed by more observations.

RLOF-fed transient systems in outburst reach high (close to Eddington) X-ray luminosities. We introduce a factor $\eta_{bol}$ describing the fraction of the critical Eddington luminosity a given system has reached. The long period systems, with orbits that are sufficiently extensive for a large accretion disk to be formed, are usually found to emit at the Eddington luminosity ($L_{edd}$) during outburst, while the outburst luminosities of short period systems are lower by about an order of magnitude. The correction factor to an X-ray luminosity at outburst corresponding to $\eta_{out} = 0.1$ and $\eta_{out} = 1$ for the short and long period systems is applied respectively. The critical periods, above which the Eddington luminosity is adopted, are taken to be 1 day and 10 hrs for NS and BH transients in outburst, respectively (Chen, Shrader & Livio 1997; Garcia et al. 2003; see also appendix A1 in Portegies Zwart, Dewi & Maccarone 2004).

In order to decide if a given transient system is in an active (outburst) state or inactive (quiescent) state the disk duty cycle ($DC_{disk}$; the fraction of a time a given system spends in the outburst) must be known. However, the disk instability theory cannot provide a reliable estimate of $DC_{disk}$. Empirically it is thought that $DC_{disk} \leq 1\%$ (e.g., Taam, King & Ritter 2000). We adopt $DC_{disk} = 1\%$ (probability of finding a system in outburst) in our calculations and use Monte Carlo to decide the state of a transient system. In practice when we study a stellar population the information for all X-ray binaries is extracted at some specified time (time slice). Once a given system is identified as a transient (see eq. [22] a random number (flat probability distribution) is drawn from the range 0–1. If the number is smaller than 0.01 (1% probability) the system is then in outburst, otherwise it is in quiescence. The appropriate X-ray luminosity is then assigned to the system (see eq. [23]). Alternatively, we use a phenomenological model for the duty cycle developed by Portegies Zwart et al. 2004. The model is based on the observations available for the Galactic BH transient systems. In particular comparison of the recurrence time and the decay time combined with the observed peak outburst energy allows to calculate the time in which system is brighter than a certain critical X-ray luminosity. Specific application of that model will be discussed in the forthcoming paper on the evolution of X-ray luminosity function in starburst galaxies (Belczynski et al. 2006, in preparation).

Finally, the bolometric accretion luminosity is converted to an X-ray luminosity in a specific energy range. We perform the conversion to the 0.3 – 7 keV range, which may be used directly for comparison with Chandra observations. For all the persistent RLOF-fed sources, all wind-fed sources and the transients in the outburst stage, where accretion is the dominant contributor to the observed luminosity, we apply a bolometric correction ($\eta_{bol}$). For all quiescent transients the bolometric correction is not needed since we adopted their X-ray luminosities directly from observations. For different types of systems we estimate the correction to be:

$$\eta_{bol} = \begin{cases} 0.15 & \text{NS: wind; all} \\ 0.55 & \text{NS: RLOF; pers., outburst trans.} \\ 0.8 & \text{BH: wind; all} \\ 0.8 & \text{BH: RLOF; pers., outburst trans.} \end{cases}$$

(83)

Corrections were obtained from: La Barbera et al. (2001) for wind-fed NS systems; from Di Salvo et al. (2002) and Maccarone & Coppi (2003) for RLOF-fed NS systems; and from Miller et al. (2001) for BH systems. These bolometric corrections will be applicable for the typical Chandra observations of external galaxies. For deeper observations, where the lower luminosity cutoffs are below a few percent of the Eddington limit, the objects make spectral state transitions (see Maccarone 2003 and references within), and the bolometric corrections are much larger.

Combining all of the above information, we can calculate the X-ray luminosity of synthetic X-ray binaries from

$$L_x = \begin{cases} 10^{31} - 10^{32} & \text{all quiescent NS transients} \\ 10^{30} - 10^{32} & 80\% \text{ quiescent BH transients} \\ 10^{32} - 10^{33} & 20\% \text{ quiescent BH transients} \\ \eta_{bol}L_{bol} & \text{outburst NS/BH transients} \\ \eta_{bol}L_{bol} & \text{persistent (RLOF and wind)} \end{cases}$$

(84)

where $L_x$ is expressed in erg s$^{-1}$ and $L_{edd}$ represents the Eddington luminosity. Note that the X-ray luminosity is calculated directly from the mass transfer rate only for persistent sources. On the other hand, we adopt the above empirical description for transient sources since the relation between the quiescent, outburst, bolometric luminosities, and duty cycle are uncertain due to the mass loss from the system during the outburst state. Evidence for such mass loss in the form of jets and/or wind have been observed in, for example, a Galactic BH transient GRS 1915-105 (Dhawan, Munu & Remillard 2005; Truss & Done 2006).

9.2. High Mass X-ray Binaries: Be Star Transients

9.2.1. Observational Overview

High mass X-ray binaries consist of a compact object (either a NS or a BH) orbiting a massive star. Both galactic and extra-galactic populations of HMXBs are known (Liu, van Paradijs & van den Heuvel 2000, 2005). The
majority of HMXBs (about 2/3; see Liu et al. 2000, 2005; Hayasaki & Okazaki 2005) are so-called Be/X-ray binaries, in which the primary is a Be star, orbiting a magnetized NS. Orbits are generally wide with a moderate eccentricity. The compact star accretes from the wind of a massive main sequence or subgiant Be (spectral types B3-O with Balmer emission lines; Zorec & Briot 1997) companion. Many of these systems show transient behavior (see below). The remaining HMXBs are those in which the primary is a supergiant, so called SG/X-ray binaries (e.g., Liu et al. 2000). For these systems the compact object either accretes from the wind of the supergiant, or in brighter systems through RLOF (possibly atmospheric but not always) via an accretion disk.

If indeed some HMXBs are confirmed to be evolving through stable RLOF, it should pose a useful constraint on the development of a delayed dynamical instability. In general, it is expected that mass transfer from a much more massive donor to a low mass companion is dynamically unstable and leads to the formation of a CE (see §5) that ends HMXB phase. It has been shown that if a H-rich donor is ∼3 times more massive than a compact star accretor (see §5.1) the RLOF will lead to CE phase. For adopted the maximum NS mass adopted here (2.5 M⊙) we predict that only stars of spectral type later than B3 (masses smaller than 7.5 M⊙) could be in dynamically stable RLOF with NS accretors. If a higher mass donor is found in a HMXB with a solid case for ongoing RLOF, then either i) compact object mass is higher (e.g., BH), or ii) the system is in the phase of short-lived atmospheric RLOF and will soon end up in CE phase, or iii) the understanding of development of dynamical instability is incomplete and the observations could be used to set new limits.

Some Be/X-ray binaries (Be XRBs) are persistent sources (varying by less than a factor of ∼10) observed at low luminosity levels Lx ∼ 10^32 − 10^34 erg sec^−1 (e.g., Van Bever & Vanbeveren 2000; Okazaki & Negueruela 2001). However, most Be XRBs show periodic outbursts and are called transient Be XRBs. Transient Be XRBs exhibit two different types of outbursts (e.g., Bildsten et al. 1997; Okazaki & Negueruela 2001; Hayasaki & Okazaki 2005; Baykal et al. 2005): (i) Type I (normal) outbursts, which are of moderate intensity (∼ 10^{36} − 10^{37} erg sec^−1) and they appear to be related to the orbital period. It is generally accepted that these outbursts are associated with the periastron passage of a NS, and are explained by the increased accretion from the Be star wind at periastron. (ii) Type II (giant) outbursts, with luminosities reaching Lx ≥ 10^{37} erg sec^−1, are irregular, and although they seem to appear shortly after the periastron passage, they do not exhibit any other correlations with the orbital period. Although the origin of the Type II outbursts remains unknown, it was suggested that the outflow from the Be star may lead to the formation of a transient accretion disk around the NS. Disk accretion results in higher X-ray luminosities than direct surface wind accretion (see Bildsten et al. 1997 for a discussion and references). Some systems show both types of outbursts, e.g., A 0535+262 (Motch et al. 1991; Finger, Wilson & Harmon 1996), V0332+53 (Stella, White & Rosner 1986) or 4U 0115+634 (Baykal et al. 2005).

9.2.2. Modeling

Type I outbursts are averaged out of our calculations if we use the orbit-averaged wind accretion model (see §4.2). In the general (arbitrary eccentricity) wind accretion model (see §4.1) Type II outbursts are a natural outcome. However, it was noted (Avni & Goldman 1980) that the transient phenomenon may be difficult to explain.

We construct a simple phenomenological model for Type II outbursts in order to be able to assess the influence of this transient activity on XRB population characteristics. For a system to be a potential Type II Be XRB outburster we require:

− a binary with a NS or a BH accretor and a massive MS (K_1 = 1) or subgiant (K_1 = 2) donor (M ≥ 8 M⊙, spectral type earlier than B3),

− that the system is tight enough so it appears as a HMXB with a persistent (outside outbursts) wind accretion leading to an X-ray luminosity greater than L_{x,Be}. We allow L_{x,Be} to change within the range 10^{32} − 10^{34} erg sec^−1.

Furthermore, only a fraction (f_{Be}) of donors in the above binaries are Be stars (as opposed to a regular B stars), and can potentially trigger the Type II outbursts. To provide an upper limit on the contribution of bursting HMXBs to the XRB population one may choose f_{Be} = 1. For detail studies, the value of f_{Be} may be constrained based on the age of a massive star (McSwain & Gies 2005) or its spectral type and luminosity class (Zorec & Briot 1997). Since little is known about the duty cycle of Type II outbursts, we allow the duty cycle to change within a wide range D_{C,Be} = 0.1 − 0.5 and use Monte Carlo to decide whether the system is in outburst or in quiescence. Here, D_{C,Be} gives the fraction of a time a given system spends in the outburst. An orbit averaged X-ray luminosity (direct wind accretion) is used for quiescence (η_bol = 0.15, 0.8 §9.1), although thermal emission from a NS is also observed in some systems. For systems in the Type II outburst the X-ray luminosity is taken to be uniformly distributed in the range L_{x} = 10^{37} − 10^{38} erg sec^−1. We adopt bolometric correction factors: η_{bol} = 0.15, 0.8 for NS and BH accretors, respectively (see §9.1).

The X-ray modeling will be further developed as we proceed with the studies of the Galactic and extragalactic X-ray binary populations (e.g., Belczynski et al. 2006, in preparation).

10. SUMMARY

We have presented a detailed description of the updated StarTrack population synthesis code. The code is being used to study populations of different varieties of binaries hosting compact objects. The code has been calibrated and tested against different sets of observations and detailed evolutionary calculations and the results are presented here. The updated version of StarTrack was already used in several studies of compact object binaries and XRBs. StarTrack allows for evolution of stellar systems with a wide variety of different initial conditions (IMF, metallicity, star formation history) and for a number of different evolutionary models, subject to the parametrization of the input physics.

The StarTrack code can be compared to the BSE population synthesis code (Hurley et al. 2002). StarTrack
incorporates the same single star evolutionary formulas (Hurley et al. 2000) as the BSE code, however we extend the original formulas to i) include wind mass loss rates from low- and intermediate-mass main sequence stars (formation of pre-LMXBs, Belczynski & Taam 2004b); ii) account for the late evolution of low-mass helium stars (new formation channels of double neutron star systems, see Belczynski et al. 2006 and references therein); and iii) calculate final masses of neutron stars and black holes, based on recent hydrodynamical calculations (e.g., Belczynski et al. 2004b), which results in more realistic (as compared to observations) BH masses than obtained with the BSE code. For the treatment of tidal interactions we use the same equations (ODEs) as in Hurley’s code, but we employ numerical integration of the ODEs instead of simple multiplication of the derivatives by the evolutionary timestep. We also adopt convective tides that are more efficient (by a factor of 10-100) based on the observational calibration discussed in section 8.2. This will have a significant effect on the evolution of close binaries with low mass (convective) stars. The calculation of X-ray luminosities for transient systems with NS and BH accretors is much more comprehensive in StarTrack. We use both the recent theoretical work and observations of low- and high-luminosity X-ray sources, to calibrate and test our approach (Belczynski & Taam 2004b; Belczynski et al. 2004a). The compact object masses formed in core collapse are calculated differently, and in particular we account for possibility of direct BH formation (no natal kick, no mass loss), with maximum BH masses formed reaching 10–20 M⊙ depending on metallicity and adopted wind mass loss rates (e.g., Belczynski et al. 2002; Belczynski et al. 2004b), a result that is consistent with maximum BH mass estimates in Galactic BH binaries (e.g., 15 M⊙ for GRS 1915; 10–19 M⊙ for Cyg X-1; see Orosz 2003) In contrast, in the BSE code all compact objects (including BH) have masses below 2.5 M⊙ for the entire spectrum of initial progenitor masses and different metallicities (see Fig.20 of Hurley et al. 2000), a result that cannot be reconciled with the current estimates of BH masses. Also more recent (Arzoumanian et al. 2002; Hobbs et al. 2005) natal kick distributions are used here as compared to Lyne & Lorimer (1994) in BSE. The above will affect the post-SNα binary orbit, and subsequent evolution of massive binaries. For example, the effect of natal kicks on population of double compact objects is rather dramatic and was quantified in Belczynski et al. (2002c). The treatment of nuclear mass transfer rate is different in the two codes. In BSE it is calculated using a formula that keeps the donor star within its Roche lobe. The formula is calibrated to keep the mass transfer steady. In StarTrack, we use the radius-mass exponents for the donor and its Roche lobe along with an estimate of the evolutionary donor radius change with time to calculate the mass transfer rate (see Sec. 5.1). The calibration of the BSE prescription is not discussed in detail by Hurley et al. (2002). Ruijter et al. (2006) find that for intermediate polars (low mass main sequence donors with WD accretors) the BSE code results in mass transfer rates of about 2 orders magnitude lower (as calculated by Liu & Li 2006) than the rates predicted by StarTrack and the observations of intermediate polars may indicate (Muno et al. 2006). For low mass binaries, we use a different (less efficient) magnetic braking law in our standard model. As a result, binary orbits in our model will tend to take longer time to decay and initiate mass transfer, as compared to BSE models. The StarTrack prescription of mass accumulation onto white dwarfs is quite unique (see § 5.7). Related results of calculations for accretion induced collapse and NS formation were presented by Belczynski & Taam (2004a) and progenitor models of SN Ia by Belczynski et al. (2005b). On the other hand, the BSE code is more fitted to work with dynamical codes, following in detail merger products (and their evolution) of various types of binary components. Also, the BSE code is much faster than the StarTrack code, and therefore may be used for simulations of larger stellar populations.

In a series of papers that will follow we will address the issues of modeling of XRBs, and will focus on the comparison of synthetic XRB populations with the observed X-ray point source populations in nearby galaxies. The code is also being used to study populations of binaries with NSs and BHs as potential source candidates for ground based interferometric gravitational radiation observatories (e.g., GEO, LIGO, VIRGO) as well as populations of less-massive WD binaries for space-based projects (e.g., LISA).

Although a number of physical processes governing single and binary evolution remain highly uncertain, the advances in observational techniques and new results of massive surveys allow now various aspects of stellar evolution to be explored. We have incorporated several different evolutionary models within StarTrack (e.g., different magnetic braking laws or CE prescriptions) making possible tests of their validity. For example, one such test may be based on a comparison of synthetic and observed X-ray luminosity functions for nearby starburst galaxies.

The StarTrack code described in this paper may be used only for the evolution of isolated stars and binaries, i.e., in stellar systems in which dynamical interactions are not important (e.g., field populations, open clusters). However, a number of interesting studies may be carried out for dense stellar environments, in which both stellar evolution and dynamical interactions play an important role in the formation of compact object binaries. In particular, StarTrack was integrated with a dynamical code for these types of studies (for details see Ivanova et al. 2005).

We would like to thank R. Webbink, G. Nelemans, T. Di Salvo, J. Sepeinsky and A. Ruiter for useful discussions and comments on the manuscript. KB and TB acknowledge partial support through KBN Grant 1P03D02228 and 1P03D00530, and KB acknowledges support through NASA Chandra Theory Grant TM6-7006X. VK acknowledges support through a David and Lucile Packard Foundation Fellowship in Science and Engineering and through NASA grants NAG5-13056 and NASA-03060. In addition, this research was supported in part by the NSF under Grant No. AST-0200876 to RT.

Fig. 1.— Final compact object masses in function of initial mass for single star evolution (with solar metallicity and standard winds). Top panel shows the full mass range, and indicates pre-collapse mass of the progenitor star. Bottom panel shows the mass range important for NS formation, with different types of remnants marked on the plot. For discussion see §2.3.1.
Fig. 2.— Initial rotational velocities of stars used in StarTrack calculations. In the top panel we present the fit to the observational data from Stauffer & Hartmann (1986). In the bottom panel we show the ratio of the data and the model.
Fig. 3.— The diagnostic diagram (top panel) used to decide whether a binary should be evolved on a thermal timescale or rather RLOF is dynamically unstable (leading to CE evolution and a potential merger). If the mass ratio at the onset of RLOF \(q_{\text{init}}\) is much greater than the mass ratio at the moment when the orbit starts expanding \(q_{\text{low}}\) then the system is dynamically unstable, otherwise RLOF on a thermal timescale is assumed. The arrow represents the partial derivative of donor radius (equal to the Roche lobe radius) with respect to its mass, and points to the place where the donor is expected to regain thermal equilibrium. The bottom panel shows a specific system: a 16 M\(_{\odot}\) Hertzsprung Gap donor with a 15 M\(_{\odot}\) MS companion in an 8-day orbit, for which the diagnostic diagram is plotted. The mass transfer begins on a thermal timescale (flat part) and then evolves on a slower nuclear timescale (decline). For more details see §5.2.
Fig. 4.— The case of a binary disrupted in a supernova explosion: we present the orbit in the coordinate system $III$ (for details see §6). The line OA is parallel to the vector $\vec{n}_{\text{int}}^{III}$, while the line OB, the asymptote of the hyperbola, is parallel to the vector $\vec{n}_{\text{fin}}^{III}$. The point O is the focus of the hyperbola.

Fig. 6.— RLOF sequence for 12 M⊙ MS + 7.5 M⊙ MS binary. Panels same as in Fig. 5.
Fig. 7.— RLOF sequence for 10 M⊙ BH + 5 M⊙ MS binary. The critical Eddington mass accretion rate onto the BH is about $3.1 - 4 \times 10^{-7} M_\odot \text{yr}^{-1}$. Panels same as in Fig. [\ref{fig:5}].
Fig. 8.— RLOF sequence for $7 \, M_\odot$ BH + $2 \, M_\odot$ RG binary. The critical Eddington mass accretion rate onto the BH is about $2.2 - 2.6 \times 10^{-7} \, M_\odot \, \text{yr}^{-1}$. Panels same as in Fig. 5.
Fig. 9.— RLOF sequence for 1.3 Mₜₜ NS + 1.6 Mₜₜ RG binary. The critical Eddington mass accretion rate onto the NS is \( \sim 1.7 \times 10^{-8} \, M_{\odot} \, \text{yr}^{-1} \). Panels same as in Fig. 5.
Fig. 10.— RLOF sequence for 1.3 $M_\odot$ NS + 1 $M_\odot$ RG binary. The critical Eddington mass accretion rate onto the NS is $\sim 1.7 \times 10^{-8} M_\odot$ yr$^{-1}$. Panels same as in Fig. [5].
Fig. 11.— RLOF sequence for 1.4 M⊙ NS + 2.8 M⊙ evolved He-star binary. The critical Eddington mass accretion rate onto the NS is \( \sim 2.9 \times 10^{-8} \text{ M}_\odot \text{ yr}^{-1} \). Panels same as in Fig. \[\text{Fig. 5}\] Note the very short duration of this RLOF phase; the (finite) timesteps taken by the code may be seen through lines showing orbital period and donor mass.
Fig. 12.— RLOF sequence for 1.4 $M_{\odot}$ NS + 3.6 $M_{\odot}$ evolved He-star binary. The critical Eddington mass accretion rate onto the NS is $\sim 2.9 \times 10^{-8} M_{\odot}$ yr$^{-1}$. Panels same as in Fig. 5.
Fig. 13.— Tidal calibration calculation for the open cluster M67. The figure shows the period–eccentricity plane with the population of main sequence binary stars at 3.98 Gyr, the current age of the cluster. Bottom and middle panels show the results of evolution with increased tidal interactions ($F_{\text{tid,con}} = 100, 10$, respectively) as opposed to the standard prescription, presented on the top panel ($F_{\text{tid,con}} = 1$). Note the increase of cutoff period (the longest period circular binary in a given sample) with increasing $F_{\text{tid,con}}$. The observed cutoff period for M67 is $P_{\text{cut}} \simeq 10 - 12$ days. For more details see §8.2.1.
Fig. 14.— Tidal calibration calculation for the high-mass X-ray binary LMC X-4. The observed orbital decay rate for LMC X-4 is $-9.8 \times 10^{-7}\text{yr}^{-1}$ (marked with dotted line). Predicted decay rates for different radii of the main sequence secondary in respect to its Roche lobe ($R_2/R_{2,\text{lob}} = 0.75, 0.8, 0.9$) are shown for $F_{\text{tid,rad}} = 1, 10$. For more details see § 8.2.2.
