We investigate a hybrid quantum circuit where ensembles of cold polar molecules serve as long-lived quantum memories and optical interfaces for solid state quantum processors. The quantum memory realized by collective spin states (ensemble qubit) is coupled to a high-Q stripline cavity via microwave Raman processes. We show that for convenient trap-surface distances of a few µm, strong coupling between the cavity and ensemble qubit can be achieved. We discuss basic quantum information protocols, including a swap from the cavity photon bus to the molecular quantum memory, and a deterministic two qubit gate. Finally, we investigate coherence properties of molecular ensemble quantum bits.

During the last few years we have witnessed remarkable progress towards realization of quantum information processing in various physical systems. Highlights include quantum optical systems of trapped atoms and ions [1], and cavity QED [2], as well as solid state systems including Cooper Pair Boxes (CPB) [3,4] and quantum dots [5]. In particular, the strong coupling regime of circuit QED [6] was realized using a CPB strongly coupled to a strip line cavity. In the light of these developments it is timely to investigate hybrid devices with the goal of combining the advantages of various implementations, i.e. to build interfaces between, for example, a quantum optics and solid state qubit with compatible experimental setups [7]. Such interfaces are particularly important in applications where long-term quantum memories or optical interconnects are required [8].

In this Letter we study such a scenario by coupling a strip line cavity to a cloud of cold polar molecules [9]. The cavity may be part of a solid state quantum processor involving CPB as charge qubits [3] and microwave photons as a quantum data bus, while the molecular ensemble serves as a quantum memory with a long coherence time. The condition of strong coupling between the cavity and the molecular cloud is achieved via the (large) electric dipole moments of polar molecules for rotational excitations in the electronic and vibrational groundstate, which are in the tens of GHz regime, and thus provide an ideal match for resonance frequencies of strip line cavities. By adopting a molecular ensemble instead of a single polar molecule [10], we benefit from the enhancement of the coherent coupling $g/\sqrt{N}$ with the number of molecules $N$ and $g$ the single molecule vacuum Rabi frequency. This strong coupling between the molecular ensembles and the circuit CQED system also opens the possibility of a solid state based readout of molecular qubits. In addition, qubits stored in the molecular ensemble can be converted to “flying” optical qubits, using techniques demonstrated for atomic ensembles [11]. This provides a natural interface between mesoscopic quantum circuits and optical quantum communication.

Let us consider the setup of Fig. 1 where two molecular ensembles are coupled to a superconducting cavity. The cavity is assumed to be strongly coupled to a CPB representing a circuit CQED system, as realized in recent experiments at Yale [6]. As discussed in detail below, molecular spectroscopy allows us to identify long-lived states, for example in the form of a spin qubit $|0\rangle, |1\rangle$ in the ground rotational manifold. Starting with a cloud of $N$ molecules prepared in $|0\rangle_m \equiv |0_10_2...0_N\rangle$ coupling to a microwave or cavity field leads to excitations in the form of symmetric Dicke states, $|1\rangle_m \equiv 1/\sqrt{N}\sum |0_1...1_i...0_N\rangle \equiv m^\dagger|0\rangle_m$ etc. For weak excitation the operator $m$ obeys approximate harmonic oscillator commutation relations $[m, m^\dagger] \approx 1$, and the ensemble excitations are conveniently described as a set of harmonic oscillator states $|0\rangle_m, |1\rangle_m \equiv m^\dagger|0\rangle_m$ etc. Our goal below is to use the lowest two of these states as ensemble qubits, which can be manipulated by coupling them to the superconducting cavity and a CPB.

The dynamics of the coupled system (Fig. 1a) can be described in terms of a Hamiltonian $H_{\text{sys}} = H_C + H_M + H_{CM}$, which is the sum of a Jaynes-Cummings type Hamiltonian for the circuit CQED system $H_C$, a Hamiltonian for the (spin) excitations of the molecular ensembles $H_M$, and the coupling of the molecules to the cavity $H_{CM}$. The CQED Hamiltonian has the form

\[ H_C = -\delta_c(t)|e\rangle\langle e| + g_c(|e\rangle\langle g|c + |g\rangle\langle e|c^\dagger) \quad (1) \]

Here $|g\rangle$ and $|e\rangle$ denote the ground and the first excited eigenstate of the CPB at the charge degeneracy point representing a charge qubit with a (tunable) transition frequency $\omega_{eq}(t)$ with detuning $\delta_c(t) = \omega_c - \omega_{eq}(t)$ from...
the cavity frequency $\omega_c$. The operator $\hat{c}$ ($\hat{c}^\dagger$) is the cavity annihilation (creation) operator for microwave photons of frequency $\omega_c$, and $g_c$ is the vacuum Rabi frequency. Eq. (1) is written in an interaction picture with the bare cavity Hamiltonian $\omega_c \hat{c}^\dagger \hat{c}$ transformed away. The Hamiltonian describing the internal excitations of the molecular ensembles $i = 1, 2$ and the coupling of ensemble states to the stripline cavity takes the form

$$H_M + H_{CM} = -\sum_i \delta_{m}^{(i)}(t) \hat{a}_i^\dagger \hat{a}_i + \sum_i h_{m}^{(i)}(t) \hat{a}_i^\dagger \hat{a}_i + \text{H.c.}$$

Before we enter the details of the derivation of $H_M$ and $H_{CM}$ we note the basic structure of the Hamiltonian $H_{sys}$. The ensemble excitations and the cavity represent a system of coupled harmonic oscillators interacting with a two-level system (CPB) with controllable coefficients. In general, this provides the basic ingredients for (i) swap operations between the charge, cavity and ensemble qubits, (ii) single qubit rotations of the molecular qubit via the charge qubit, and (iii) 2-qubit entanglement operations between two ensemble qubits via the cavity mode, where the charge qubit plays the role of a nonlinearity. For example, the CPB can act as a “single photon source”, i.e. we generate a superposition state of the charge qubit, which by an appropriate control sequence can be swapped over to the cavity, and is finally stored in one of the molecular ensembles, and vice versa: $(\alpha|g\rangle + \beta|e\rangle)\hat{a}_c|0\rangle_m \rightarrow |g\rangle(\alpha|0\rangle_c + \beta|1\rangle_c)|0\rangle_m \rightarrow |g\rangle|0\rangle_c(\alpha|0\rangle_m + \beta|1\rangle_m)$.

The above discussion has ignored various sources of decoherence. In the Yale experiment [1], the circuit CQED system realizes the strong coupling regime with vacuum Rabi frequency $g_c \lesssim 2\pi \times 50$ MHz. The decoherence of the charge qubit is dominated by the dephasing rate $T_2^{-1} \approx 2\pi \times 0.5$ MHz, while the photon loss rate is $\kappa/2\pi = 1$ to 0.01 MHz, i.e. the charge qubit is the dominant source of decoherence. Below we will show that for a cloud of $N \approx 10^4$ to $10^6$ molecules of temperature 1 mK, trapped at a distance 10 $\mu$m above the stripline cavity, one can reach the regime of strong cavity - ensemble coupling $g_m/2\pi \approx 1$ to 10 MHz, which should be compared with the expected collisional dephasing rates of the molecular memory of a few hundred Hz.

Fig. 1b shows the rotational spectrum of CaF, which provides an example for spectra of alkaline-earth monohalogenides with a $^2\Sigma_{1/2}$ ground state corresponding to a single electron outside a closed shell. The spectrum consists of rotational eigenstates, described by a rigid rotor Hamiltonian $H_R = B N^2$ with $B \approx 2\pi \times 10$ GHz the rotational constant, and $\tilde{N}$ the angular momentum of the nuclei. The unpaired spin is coupled to the molecule rotation according to $H_{SR} = \gamma_{sr} \tilde{S} \tilde{N}$ with $\gamma_{sr} \sim 2\pi \times 40$ MHz and $\tilde{S}$ the electron spin ($S = 1/2$). Coupled eigenstates are denoted by $|N, S, J; M_j\rangle$ with $\tilde{J} = \tilde{N} + \tilde{S}$. As seen from Fig. 1a there is a spin rotation splitting ($\rho$-doubling) for rotationally excited states. In addition, there can be hyperfine interactions, which in particular lead to a splitting of the ground state $|0\rangle$ into a pair of states in the rotational ground state manifold to provide our spin qubit. Compared to qubits stored in the rotational degrees of freedom this choice of states avoids unfavourable $N = 1 = 0$ collisions while $|0\rangle$ and $|1\rangle$ can still be coupled efficiently by a Raman process.

The cavity mode and microwave fields of appropriate frequency and polarization couple rotational ground states to excited states with electric dipole matrix elements $\mu$ ($\sim 5$ Debye). Two microwave driving fields provide an effective coupling Hamiltonian $\frac{1}{2}g_{\text{eff}}(t)|0\rangle_1|\text{c} + \text{h.c.}$ for the single molecule spin qubit, where $g_{\text{eff}} = \Omega_{12}/2\Delta$, with $\Omega_{12}$ the Rabi frequencies and $\Delta$ the detuning from the excited state $|e\rangle$, ($\Delta \gtrsim \Omega_{12}$). By similar arguments the coupling to the cavity has the form $g_{\text{eff}}(t)|0\rangle_1|\text{c} + \text{h.c.}$ with $g_{\text{eff}}(t) \equiv g\Omega(t)/2\Delta$, where $g = \mu\tilde{E}_c$ is the vacuum Rabi frequency, and $\tilde{E}_c \approx \sqrt{\hbar\omega_c/2e\text{c}}L$ is the electric field per photon for a cavity length $L$ and typical electrode distance $d$. Typical values are $g/2\pi \sim 5 - 10$ kHz for $\mu \approx 5$ D and $d \approx 10 \mu$m. The distance $d$ is also an estimate of the trapping distance of the molecular cloud from the cavity, which is well in the limit where standard trapping techniques work reliably and surface effects are negligible. Rewriting $H_{CM}$ in terms of the collective operator $m$ we obtain an effective cavity - ensemble coupling $g_m(t) = \sqrt{N}g_{\text{eff}}(t)$. Due to the large wavelength $\lambda_c \approx 1.5$ cm a trap volume of $V \lesssim d \times d \times \lambda_c/10$ contains $N \approx 10^4 \ldots 10^6$ molecules for gas densities of $n \approx 10^{12}$ cm$^{-3}$ resulting in a coupling strength of $g_m/2\pi \approx 1 - 10$ MHz. The parameters $\delta_m^{(i)}(t)$ are Raman detunings, which can be controlled independently, e.g. by applying local magnetic and/or electric fields. Thus we obtain the Hamiltonian $H_M + H_{CM}$,
which allows a SWAP of a cavity and an ensemble state, for example, by an adiabatic sweep of $\delta_m$ across the resonance. This corresponds to a read / write operation $\rho_c \otimes |0\rangle_0 \otimes |0\rangle_c \rightarrow |0\rangle_c |0\rangle_0 \otimes \rho_m$ with $\rho_c$, an arbitrary density operator of the microwave field in the cavity, and $\rho_m$ the identical state stored in ensemble excitations.

The CPB provides a nonlinear element in the Hamiltonian $H_{\text{sys}}$. This allows first of all single qubit operations of ensemble qubits, e.g. by combining a swap operation with single qubit rotations of the charge qubit, and second, deterministic entanglement operations of qubits stored in two molecular ensembles. An example of such a protocol, which uses the CPB as a nonlinear phase shifter, is given as follows. We assume that the system is initially prepared in the state $|\psi\rangle_{t=0} = |\psi\rangle_m |0\rangle_c |g\rangle$ with the charge qubit far detuned from the cavity resonance, $|\delta_c(0)\rangle \gg g_c$, and the two ensemble qubits in an arbitrary state $|\psi\rangle_m$ spanned by the basis $|\epsilon\rangle_m$, $\epsilon = 0, 1$. In a first step, in analogy to the single qubit swap, the state $|\psi\rangle_m$ is (partially) transferred to the cavity. Assuming symmetric conditions, $g^{(1)}_m = g^{(2)}_m$ and $\phi^{(1)}_m(t) = \phi^{(2)}_m(t)$ it is convenient to rewrite the ensemble state in terms of the (anti)symmetric operators $m_{s/a} = (m_1 \pm m_2)/\sqrt{2}$ acting on $|00\rangle_m$. An adiabatic sweep of the Raman detunings then realizes the swap operation $m^0_{s/a} |00\rangle_m |0\rangle_c \rightarrow |00\rangle_m |c\rangle$, and $m^2_{s/a} |00\rangle_m |0\rangle_c \rightarrow \sqrt{2} |00\rangle_m |2\rangle_c$, while the states $|00\rangle_m |c\rangle$, $m^0_{s/a} |00\rangle_m |0\rangle_c$, and $m^2_{s/a} |00\rangle_m |0\rangle_c$ remain unaffected. In a second step, the charge qubit is adiabatically tuned close to resonance for a time $T$, $|\delta_c(T/2)| \ll g_c$. During this pulse the non-vacuum states acquire a nonlinear dynamical phase, $|n\rangle_c \rightarrow e^{i\phi_m(n)}|n\rangle_c$ with $\phi_m = -\int_0^T dt' (\dot{\delta}_m(t')) + \sqrt{2} |g_m(t')|^2 / 2$. The pulse form $\delta_c(t)$ and the length $T$ are chosen such that $\phi_1 \approx \pi/2$ and $\phi_2 = 2\pi n$ (see e.g. Fig. 2). The second condition ensures that after writing the cavity state back into the ensembles states, i.e. reversing step one, the ensemble states $|20\rangle_m$ and $|02\rangle_m$ remain unpopulated. The total gate sequence corresponds to a $\sqrt{\text{SWAP}}$-like gate for two ensembles qubits, with $|00\rangle_m \rightarrow |00\rangle_m$, $|10\rangle_m \rightarrow e^{i\pi/4} (|10\rangle_m + i |01\rangle_m)/\sqrt{2}$, $|01\rangle_m \rightarrow e^{i\pi/4} (|01\rangle_m + |10\rangle_m)/\sqrt{2}$ and $|11\rangle_m \rightarrow |11\rangle_m$. A numerical simulation of this gate sequence based on a master equation treatment of the dissipative terms shows that the gate fidelity is only limited by $(g_c T_2)^{-1}$ i.e. the decoherence of the CPB during the time it is tuned close to resonance (see Fig. 2 for more details).

We now turn to an analysis of decoherence in the molecular ensemble. In particular collisional dephasing of the ensemble qubit, and a spatial variation of the cavity-molecule coupling $g_{\text{off}}(x)$ in combination with the thermal motion of the molecules in the trap contribute to a finite decoherence time of the molecular quantum memory, and result in imperfections during gate operations.

An operational definition of the decoherence time of the ensemble qubit can be given in terms of an (idealized) experiment. A cavity qubit $\rho_c(t = 0) = |\psi\rangle_c \langle \psi\rangle$ with $|\psi\rangle_c = |\alpha\rangle_c + |\beta\rangle_c$, is written at time $t = 0$ to the molecular memory with all molecules initialized in the state $|0\rangle$ in a (perfect) swap operation, kept in storage for a time interval $\tau$, undergoing dephasing collisions. At $t = \tau$, the qubit is transferred back to the cavity mode, resulting in a reduced density matrix $\rho_c(\tau)$ of the cavity with a fidelity $F_\tau = \min_{\psi_c} \langle \psi_c | \rho_c(\tau) | \psi_c \rangle$, with the decoherence time of the ensemble memory identified as the decay time of the fidelity. The analysis of this process resembles the discussions of clock shifts, and in particular studies of collisional dephasing of spins in thermal and quantum degenerate atomic clouds in a Ramsey interferometry setup. A formal theoretical description of these phenomena is provided by quantum kinetic theory.

We consider a thermal cloud of molecules in the lowest rotational state with qubits stored in spin or hyperfine states (Fig. 1). Molecules in the rotational ground state interact asymptotically according to a $V(r) \simeq -C_0/r^6$ potential with $C_0 = (\mu^2/4\pi\epsilon_0)^2/6\beta a$. The effective range of this potential is given by $R_c = \sqrt{mC_0/\beta^2}$, which provides an estimate for the s-wave scattering length $\tilde{a}$. For example, for CaCl (which has two magnetically trapped hyperfine states) we obtain $R_c \approx 780 a_B$ which is a few times the typical scattering length encountered for alkali atoms. S-wave scattering dominates for temperatures $T \lesssim T_* \approx 1 \mu K$ where the thermal energy is below the centrifugal barrier for higher angular momenta, leading to an estimate for the collision rate $\gamma_{\text{col}} = 8\pi^2 n^2 \bar{v} \approx 2\pi \times 150 \text{ Hz}$ for $n = 10^{12} \text{ cm}^{-3}$ and $\bar{v}$ the relative thermal velocity. For temperatures $T \gg T_*$ higher partial waves contribute, and an estimate of the cross section based on the unitarity limit gives $\gamma_{\text{col}} \lesssim 2\pi \times 700 \text{ Hz}$ for $T = 1 \text{ mK}$. In electric traps the induced dipole moments, $\mu_{\text{ind}}$, lead to a $V(r) \propto \mu_{\text{ind}}^2/r^3$ dependence of the asymptotic interaction. Although this long-range behavior significantly changes the low temperature scattering ($T < 1 \mu K$) the
estimate based on the unitarity limit at $T \approx 1$ mK still provides a valid bound for scattering rates of weakly polarized molecules ($\mu_{\text{ind}} < 1$D).

We have calculated the decoherence time of an ensemble qubit corresponding to collisional dephasing using quantum kinetic theory \[14\]. Dephasing of the qubit coherence ($\rho_{10}(\tau) = \exp(-\gamma_{10} \tau/2)\rho_{10}(0)$) is associated with spin dependent collisions between the states $|0\rangle$ and $|1\rangle$, which gives a contribution

$$
\gamma_{10} = \frac{2k^3n}{m^2} \int \prod_{i=1}^{4} d^3k_i \frac{\delta(\Delta E(K)) \delta(K) P(k_1)P(k_2)}{2} \times [(f_{00}^e(K) - f_{01}^e(K))^2 + |f_{00}^g(K)|^2 + |f_{01}^g(K)|^2].
$$

It depends on the difference between $f_{00}$ and $f_{01}$, the elastic scattering amplitudes for the internal states $|0\rangle$ and $(|10\rangle + |01\rangle)/\sqrt{2}$ averaged over the thermal distributions $P(k)$ in the scattering process between momenta $K = (k_3, k_4 \leftarrow k_1, k_2)$, and $\delta$-functions accounting for energy and momentum conservation in the collision. In addition, there may be contributions from inelastic collisions, $f_{00}^n$ and $f_{01}^n$, which scatter molecules outside the $|0\rangle$, $|1\rangle$ subspace. While accurate scattering amplitudes for molecular collisions may not be available at present, we can estimate these contributions in certain limits. For s-wave scattering the above expression simplifies to $\gamma_{10} = 8\pi(a_{00} - a_{01})^2n\bar{v}$ with $a_{00}$ and $a_{01}$ scattering lengths. If we assume that the scattering length is dominated by a spin exchange potential, the scattering is characterized by a singlet ($a_S$) and triplet scattering length ($a_T$). In the simple case of a pure spin qubit $\{|0\rangle, |1\rangle\} \equiv \{|S=1/2, m_s = \pm 1/2\}$ we find $a_{00} = a_{01} = a_T$, and the dephasing rate is determined by non-vanishing contributions arising from magnetic dipole and spin rotation coupling, which are expected to be much smaller. In a similar way, in the presence of hyperfine interactions we can form a qubit $|0\rangle = |F=I+1/2, M_F = F\rangle$ and $|1\rangle = |F=I-1/2, M_F = F\rangle$, where again $|00\rangle$ and $|01\rangle + |10\rangle$ contain no spin singlet contribution and the leading dephasing term vanishes. In the worst case the decoherence rate is bounded by the single molecule collision rate $\gamma_{\text{col}}$ which has been estimated above.

Spatial variations of the effective single molecule-cavity coupling, $g_\text{eff}(x)$, result in a dephasing of the qubit during a single swap gate and an incomplete recovery of the state after a redistribution of the molecules between two successive write/read operations. The inhomogeneity in the coupling arises from the variation of the cavity mode function on a scale of the electrode distance, $g(x) \approx g(1 - \alpha x/d)$, with $\alpha$ a numerical constant, and a position dependence of the detuning $\Delta(x) \approx \Delta - m\omega_x^2 x^2/2h$. Here $\omega_x^2 = \omega_T^2 - \omega_F^2$ accounts for a difference in the trapping potentials for the qubit states ($\omega_T$) and the excited state ($\omega_F$). For an optimal detuning $\Delta_x \approx \sqrt{3g^2N(k_bT/\hbar\omega_x^2)^2/\hbar\omega_T^2\hbar^2}$ the inhomogeneous coupling results in a total gate error of $\epsilon \approx \alpha^2(k_bT/\hbar\omega_x^2\hbar^2) + (k_bT/\hbar\omega_x^2/\hbar^2)^2/3$. For $g\sqrt{N} \sim 2\pi \times 10$ MHz, $\kappa \sim 2\pi \times 10$ kHz and at $T = 1$ mK gate fidelities of $F > 0.99$ require trap frequencies of $\omega_T \sim 2\pi \times 50$ kHz and a similar trapping potential for the state $|F\rangle$ ($\delta\omega_x^2 \approx 0.1\omega_T^2$). Lower temperatures and an optimized cavity / trap design, e.g. $\alpha, \delta\omega_x^2 \to 0$, lead to a further significant reduction of gate errors.

In conclusion, thermal ensembles of cold polar molecules represent a good quantum memory that can be strongly coupled to strip line cavities with long life time, limited essentially only by collisional dephasing. We note that these dephasing channels can be virtually eliminated, if the ensemble is prepared in a high-density crystalline phase of dipolar gases with dipole moments induced and aligned by a DC electric field under 2D trapping conditions \[17\]. The present work opens an exciting avenue towards long lived molecular quantum memory for solid state quantum processors.

[14] Note that magnetic trapping achieved using localized magnetic fields near the nodes of the strip-line resonator should not significantly degrade the quality of the superconducting cavity.
