Abstract

Aims. We present $^{56}\text{Ni}$ mass estimates for seventeen well-observed type Ia supernovae determined by two independent methods.

Methods. Estimates of the $^{56}\text{Ni}$ mass for each type Ia supernova are determined from (1) modeling of the late-time nebular spectrum and (2) through the combination of the peak bolometric luminosity with Arnett’s rule. The attractiveness of this approach is that the comparison of estimated $^{56}\text{Ni}$ masses circumvents errors associated with the uncertainty in the adopted values of reddening and distance.

Results. We demonstrate that these two methods provide consistent estimates of the amount of $^{56}\text{Ni}$ synthesized. We also find a strong correlation between the derived $^{56}\text{Ni}$ mass and the absolute $B$-band magnitude ($M_B$).

Conclusions. Spectral synthesis can be used as a diagnostic to study the explosion mechanism. By obtaining more nebular spectra the $^{56}\text{Ni}$–$M_B$ correlation can be calibrated and can be used to investigate any potential systematic effects this relationship may have on the determination of cosmological parameters, and provide a new way to estimate extra-galactic distances of nearby type Ia supernovae.

Key words. stars: supernovae: general

1. Introduction

Type Ia supernovae (hereafter SNe Ia) are a vital tool for our understanding of the universe. Due to their high luminosities and remarkable uniformity they are excellent cosmological distance indicators, and allow us to determine the evolution of cosmic expansion (see e.g. Leibundgut 2001, and references therein).

SNe Ia are used as high precision cosmological probes (see Riess et al. 2004, Astier et al. 2006). To maximize the level of precision achieved from current and future experiments requires the ability to understand and reduce any source of systematic error. The main motivation of this work was thus to learn more about the relationship between the $^{56}\text{Ni}$ mass and peak absolute magnitude.

To understand the dependence of the absolute brightness on the $^{56}\text{Ni}$ mass requires knowledge of the progenitor system and explosion mechanism of SNe Ia. Despite considerable efforts on the theoretical side to investigate the explosion physics, our current knowledge of the ignition mechanism and subsequent flame propagation through the progenitor star is still rudimentary, and in some instances debatable (Hillebrandt & Niemeyer 2000). From an observational perspective, considerable effort has been put into supernova monitoring programs and many excellent data sets have been assembled. With these data it is now possible to conduct detailed investigations into the physical mechanism leading to the observed diversity in the SNe Ia population. Some first steps have been made in this direction, e.g. Cappellaro et al. (1997), Mazzali et al. (1998), Contardo et al. (2000), Mazzali et al. (2001), Suntzeff (2003), Benetti et al. (2005), Stritzinger et al. (2006), Branch et al. (2006).

The amount of $^{56}\text{Ni}$ produced in a SN Ia explosion is a key parameter that can be derived from observations and is important for our understanding of the luminosity decline-rate relation. In this article we demonstrate that the amount of $^{56}\text{Ni}$ computed from modeling the late-time nebular spectrum of a SN Ia is consistent with estimates obtained from the combination of the UltraViolet Optical near-InfraRed (UVOIR) bolometric light curve with Arnett’s rule (Arnett 1982). We also find a strong correlation between the derived $^{56}\text{Ni}$ mass and $M_B$. As we can now estimate the mass of synthesized $^{56}\text{Ni}$ accurately...
from fitting the nebular spectrum this method may provide a means to understand possible sources of systematic error that could effect the analysis of data from future high-z SNe Ia surveys.

The structure of this paper is as follows. In Sect. 2 we provide a brief description of the observational data considered in this study. Section 3 describes the two methods used to estimate the $^{56}$Ni mass. Section 4 contains the results, and is then followed by a discussion in Sect. 5.

2. Observational data

We have analyzed both published and unpublished photometric and spectroscopic CCD data collected by numerous groups over the past two decades. A large fraction of these observations were obtained by the Asiago group, the Center for Astrophysics group, and most recently by the European Supernova Collaboration. Data have also been taken from a variety of sources in the literature. Two selection criteria were fulfilled by each SN Ia in our sample: each event had to have comprehensive photometric $(U)BVR$-band light curves that include maximum light as well as at least one nebular spectrum. This spectrum is required for the spectral fitting method (see Sect. 3.1) while the well-sampled light curves are required to produce a reliable UVOIR light curve (see Sect. 3.2).

We were able to compile nebular spectra and photometric data for seventeen events. Table 1 lists relevant information for each event, which includes the number of nebular spectra, adopted values of reddening and distance moduli, as well as an estimate of the $B$-band light curve decline rate parameter $\Delta m_{15}(B)$.

3. Methods

In this section we provide a short overview of the two methods used to determine the $^{56}$Ni mass for each SN Ia.

3.1. Modeling nebular spectra

Here we summarize the spectral analysis method; for a more detailed description see Mazzali et al. (1997, 1998) and Stehle et al. (2005). A forthcoming publication will contain a detailed analysis of each modeled nebular spectra considered here (Mazzali, in preparation). This analysis includes constraints on nuclear abundances, mixing within the ejecta, and limits on the extinction.

The ratio between the explosion energy and the ejected mass in thermonuclear supernovae is larger compared to what is found in core collapse supernovae. As a result the ejecta in a SN Ia become transparent to $\gamma$ rays significantly earlier than in a type II SN. After $\sim 150$ days past maximum light the spectrum can safely be considered nebular. During the nebular phase the emission spectrum is formed in the dense central regions of the ejecta. It is at this location that the majority of Fe-group elements are located. As the abundance of different Fe-group elements is a direct consequence of the nuclear burning process, the modeling of this phase is an important opportunity to constrain the explosion mechanism.

Figure 1 The evolution of the modeled velocity for six SNe Ia as a function of time past maximum brightness.

Synthetic spectra were calculated for each observed nebular spectrum with a model that uses a non-local thermodynamic equilibrium (NLTE) treatment of the rate equations. The code first computes the deposition of the $\gamma$ rays and positrons from the radioactive decay using a Monte Carlo approach (Cappellaro et al. 1997). The deposition is transformed into collisional heating following the prescriptions of Axelrod (1980; see also Ruiz-Lapuente & Lucy 1992), and this is then balanced by cooling via line emission. Both forbidden and allowed transitions are included. Forbidden lines dominate the cooling, except for a few ions (Na I, Ca II) where permitted lines dominate. Line emission is computed in concentric shells within which the density and the abundances are constant. Since most lines are blends, we observe the combined effect of density and abundance distribution. The W7 model (Nomoto, Thielemann, & Yokoi 1984) is used throughout for the density distribution. A satisfactory fit with observed line profiles is made by changing the abundances in each shell. Rather than trying to fit the broadest features, which are formed by the blend of many weak lines, we instead fit the two strongest Fe-group features Fe III at 4650 Å and Fe II + Fe III at 5300 Å. This gives a more accurate estimate of the line emissivity and hence of the $^{56}$Ni mass.

Based on two infrared nebular spectra, Spyromilio et al. (2004) reported evidence for an increase of the expansion velocities as a function of time. We also find an increase in the emission line velocities of SN 1998bu. However, with the total data set considered in this study, which comprises six SNe Ia with at least two spectra (see Table 1), we cannot confirm an increase in line velocities. This is shown in Fig. 1 where we plot the velocity used in the model for the Fe nebula vs. days past maximum brightness. For expansion velocities greater than $\sim 6000$ km s$^{-1}$ the modeled nebular velocity is linearly correlated with the FWHM velocity of the two Fe lines that we fit (see Mazzali et al. 1998). For all normal SNe Ia we find some dispersion ($\sim 10\%$) about a mean value, however there is no clear trend for any evolution in the line velocities. Only SN 1991bg shows a significant decrease in line velocities. This
may be due to the ejecta not having reached the complete nebular phase when the first two spectra were obtained. Moreover, it is known that severe blending of lines occurs between velocities of 3000 to 6000 km s$^{-1}$ making it difficult to obtain a very reliable fit. For events with more than one nebular spectrum we computed the $^{56}$Ni mass for each spectrum and then averaged the estimates.

The main uncertainty affecting our estimate of the $^{56}$Ni mass (excluding uncertainties in reddening and distance) comes from the unknown contribution in the infrared (IR), which is known to increase during late-times (Sollerman et al. 2004). Some species, in particular Si, emit only in the IR, and their abundance cannot be constrained directly by modeling the optical spectrum only. However, in the best observed IR spectrum of a SN Ia in the nebular phase (SN 1998bu, Meikle, priv. comm.; Spyromilio et al. 2004) Si emission lines do not make a major contribution. Most of the IR flux is emitted from Fe and Co lines, and much of it is therefore taken into account in our models. We estimate that the error in our estimate of the $^{56}$Ni mass including errors associated with our code, the flux contribution in the IR, and possible systematic errors due to uncertain calibration of the late-time spectra, is of the order of $\sim$15% (see below).

3.2. The UVOIR light curve and Arnett’s rule

A complete description of how to derive the $^{56}$Ni mass using broad-band optical photometry is presented in Contardo et al. (2000). The overall strategy is to construct a quasi-bolometric light curve which allows us to avoid the complicated radiative transfer required to interpret single passband light curves. The early-time UVOIR light curve of a SN Ia is known to include most of the total true bolometric flux (Suntzeff 1996, Contardo et al. 2000). At maximum light the UVOIR light curve does not account for the $\sim$5% contribution of flux emitted in the IR nor any flux blue-wards of 3200 Å. These contributions add up to less than $\sim$15% of the total flux.

Following Contardo et al., the (U)BVRI photometric light curves are fitted with a 10-parameter function. This function contains no physics, rather it produces a continuous description of each light curve and a set of parameters that can be compared to one another. To calculate a UVOIR light curve each filter light curve is summed and a correction is made to account for the extinction. When $U$-band data is lacking (see Table 1) a correction based on SN 1992A (Suntzeff 1996) is applied in the manner described by Contardo et al. (2000). The absolute flux scale is set with an accurate distance estimate from SN 1992A (Suntzeff 1996; Stritzinger et al. 2006). Following Contardo et al. the (U)BVRI photometric light curves are fitted with a 10-parameter function. This function contains no physics, rather it produces a continuous description of each light curve and a set of parameters that can be compared to one another. To calculate a UVOIR light curve each filter light curve is summed and a correction is made to account for the extinction. When $U$-band data is lacking (see Table 1) a correction based on SN 1992A (Suntzeff 1996) is applied in the manner described by Contardo et al. (2000). The absolute flux scale is set with an accurate distance value$^1$. To derive the $^{56}$Ni mass we make use of Arnett’s rule (Arnett 1982), which states that at the time of maximum light the SN Ia luminosity is equal to the energy inputs from the radioactive decays within the expanding ejecta. A derivation of an empirical relation for Arnett’s rule that connects the observed luminosity at maximum light to the $^{56}$Ni mass is given in Stritzinger & Leibundgut (2003). Assuming a rise time to bolometric maximum of 19 days, this simple relation gives a total luminosity at maximum light of

$$L_{\text{max}} = 2.0 \times 10^{43} \left( \frac{M_{\text{Ni}}}{M_{\odot}} \right) \text{erg s}^{-1}. \quad (1)$$

To account for flux outside the optical and near-IR passbands a 10% correction is added to each $^{56}$Ni mass estimate obtained from Eq. (1).

Recently, we conducted an investigation (Blinnikov et al. 2006) of Arnett’s rule using synthetic light curves computed using the 1-D hydro code STELLA (Sorokina & Blinnikov 2003). This showed that with the UVOIR light curve and this 10% correction, Arnett’s rule estimates the $^{56}$Ni yield accurately to within $\lesssim$0.05 $M_{\odot}$.

4. Results

We now estimate the $^{56}$Ni mass for seventeen SNe Ia. Figure 2 contains the $^{56}$Ni mass determined from the synthetic spectral analysis of the nebular spectra plotted vs. the $^{56}$Ni mass derived from the UVOIR light curves. These values are listed in Table 2. Because we compare estimates of the $^{56}$Ni mass derived from two independent methods, our results are not affected by the uncertainties associated with the adopted reddening and distance values. We have therefore not included error bars arising from the uncertainty in these quantities. Including the uncertainties in distance and extinction for each event can lead to an uncertainty in the absolute value of each $^{56}$Ni mass estimate from $\sim$0.05 to $\sim$0.35 $M_{\odot}$ (Stritzinger et al. 2006). Instead, in Fig. 2 are plotted offsets from the line with a slope of one. These correspond to 10% (dashed lines) and 20% (dotted lines) respectively. From Fig. 2 it is evident that eleven of

\begin{figure}
\centering
\includegraphics[width=0.5\textwidth]{figure2.png}
\caption{Plot of $^{56}$Ni mass derived for seventeen SNe Ia via the late-time nebular spectrum fitting method vs. the UVOIR bolometric light curve method. Dashed and dotted diagonal lines correspond to 10% and 20% offsets from the slope of the solid line, respectively.}
\end{figure}
the seventeen SNe Ia have $^{56}$Ni masses that agree with each other to within 10%, four to within 20%, and only two differ by more than 20%.

In order to assess the intrinsic uncertainty of the spectral synthesis method we varied the size of the error bars on the $^{56}$Ni mass estimates and computed the reduced $\chi^2$. It is found that an uncertainty of 20% clearly overestimates the true random uncertainty while 10% gives a reduced $\chi^2 = 4.0$. We find that an uncertainty between 15% and 20% gives reasonable reduced $\chi^2$ values. For error bars that are 15% of the $^{56}$Ni mass estimates we obtain a reduced $\chi^2 = 1.8$. Furthermore if we include a 3-$\sigma$ clipping algorithm, which excludes one event (in this case SN 1995al) we obtain a reduced $\chi^2 = 1.16$. Clearly the error bar for SN 1995al should be larger than 15%. Moreover, events with poor quality data such as SN 1989B, which has two low signal-to-noise spectra and suffers from high values of extinction may also have an uncertainty larger than 15%. Nevertheless in the following we conclude that an average 15% uncertainty for the error bars is reasonable for the adopted uncertainties in the values of the $^{56}$Ni mass estimates from the spectral synthesis method determined with good quality data. As discussed above the $^{56}$Ni mass estimates determined via the UVOIR light curve and Arnett’s rule are accurate to within $\sim$10%. To be conservative we also adopt a 15% uncertainty for this method.

In Fig. 3 the $^{56}$Ni mass derived for each event via both methods is plotted vs. $\Delta m_{15}(B)$. The solid line in both panels corresponds to the Phillips $M_B-\Delta m_{15}(B)$ relation given in Phillips et al. (1999). Dotted lines in the left panel corresponds to the Phillips $M_B-\Delta m_{15}(B)$ relation when the adopted bolometric correction of $-0.28$ is changed to $-0.48$.

5. Discussion

The agreement between the $^{56}$Ni mass estimates shown in Fig. 2 is encouraging as these two methods are independent and use different observational data. The ability to accurately probe the explosion mechanism with one spectrum taken more than 100 days after the explosion reveals the power of the spectral synthesis method.

The range of a factor of ten in the amount of synthesized $^{56}$Ni, as indicated by the spectral synthesis method, is consistent with results obtained from pre-

---

By plotting the decline rate parameters rather than a parameter(s) set by an absolute flux scale, we bypass the effects associated with the uncertainty in the adopted distance.
vious studies of UVOIR light curves \cite{Suntzeff1996, Cappellaro1997, Contardo2000, Strolger2002, Suntzeff2003, Stritzinger2006}. The observed range in $^{56}\text{Ni}$ mass is difficult to reconcile with the current SN Ia paradigm \cite{Nomoto1984, Woosley1986, Hillebrandt2000}. i.e. the thermonuclear disruption of a Chandrasekhar-size white dwarf. This has lead to the introduction of the so-called delayed detonation model \cite{Khokhlov1991, Woosley1990, Woosley1994, Hoeftich1996}, and most recently more exotic explosion mechanisms \cite{Bravo2006}. An alternative to the Chandrasekhar mass model that addresses the observed diversity of SNe Ia properties is one involving a variable progenitor mass. There is observational evidence that sub-Chandrasekhar mass white dwarfs are a plausible candidate for the less luminous events and at least for the sub-luminous SN 1991bg-like variety of SNe Ia \cite{Mazzali1997, Cappellaro1997, Stritzinger2006}. Another possible progenitor maybe a super-Chandrasekhar mass progenitor \cite{Yoon2004, Yoon2005}.

Efforts to model the light curves of SNe Ia led to the suggestion that the absolute luminosity at maximum light [hence $\Delta m_{15}(B)$] is a direct consequence of the $^{56}\text{Ni}$ mass \cite{Arnett1982, Hoeftich1996, Cappellaro1997, Mazzali2001, Pinto2001, Kasen2006}. The strong correlation shown in Fig. 3 between the $^{56}\text{Ni}$ mass and $\Delta m_{15}(B)$ provides observational evidence that supports this hypothesis. This argument is strengthened by the excellent agreement between the Phillips $M_B-\Delta m_{15}(B)$ relation and the results in Fig. 3. With the acquisition of more nebular spectra it should be possible to calibrate the $^{56}\text{Ni}$ mass--$M_B$ relation. With this calibration one could then use a nebular spectrum to (1) determine the distance to a nearby SN Ia, and more importantly (2) address the relationship between the $^{56}\text{Ni}$ mass and the peak absolute magnitudes. This method is independent of the luminosity-decline rate relation, so distances determined through this method are not as susceptible to the secondary parameters that may affect the peak phase light curve \cite{Hamuy1996, Mazzali1998, Tripp1999, Hatano2000, Benetti2004, Benetti2005}. The late-time bolometric luminosity, however, may be susceptible to the distribution of isotopes and/or the fraction of positron kinetic energy that is deposited within the ejecta. Nonetheless, by gaining a deeper understanding of how the peak absolute brightness relates to the $^{56}\text{Ni}$ mass we increase our understanding of the explosion mechanism and any possible systematic errors incurred via this relationship.

The scatter seen between $\Delta m_{15}(UVOIR)$ and $\Delta m_{15}(B)$ hints at the complexities associated with the transfer of radiation through expanding ejecta, and how time-dependent NLTE effects influence the flux evolution of the near-IR light curves. Indeed a comparison between the near-IR light curves for events with similar values of $\Delta m_{15}(B)$ indicates a diversity in their morphology.

The knowledge afforded by the spectral synthesis method is significant and warrants further SNe Ia observational programs to obtain well-calibrated nebular spectra.
