The Nuclear Emulsion Technology and the Analysis of the OPERA Experiment Data

Tsutomu FUKUDA on behalf of the OPERA collaboration

F-lab, Nagoya University, Furo-cho, Chikusa-ku, Nagoya, 464-8602, JAPAN

OPERA is an experiment that aims at detecting the appearance of in an almost pure beam (the CNGS neutrino beam) through oscillation. OPERA is a hybrid detector that associates nuclear emulsions to electronic detectors. The nuclear emulsion provides the resolution necessary to detect CC interactions. The first physics run started in July and ended in November 2008. In this presentation, the status of the emulsion technology and of the analysis of its data is reported.

1. Nuclear Emulsion

Nuclear Emulsion is a special type of photographic emulsion made of AgBr microcrystals interspersed in a gelatin matrix. A charged particle passing through such medium ionizes the crystals along its path and produces a latent image. Upon a chemical process, the developed latent image is materialized by a line of grains of metallic Ag (0.5–1 μm diameter); typically the grain density is about 30 grains / 100 μm (Fig. 1). Nuclear emulsion is a sub-micron 3D tracking detector with a resolution of 0.3 μm. In particle physics, the nuclear emulsion technology is notably reputed for the discovery of the pion [1] and of the charm particle in cosmic-ray [2] and for the first observation of the tau-neutrino [3].

![Microscopic Image](image)

Figure 1: A charged particle track in nuclear emulsion.

2. The OPERA Experiment

In 1962, Maki, Nakagawa and Sakata proposed that oscillation may exist between massive neutrinos of different flavors [4]. In 1998, the Super-Kamiokande experiment established the deficit in atmospheric due to their disappearance through the oscillation mechanism [5]. This has been confirmed later by the K2K [6] and then the MINOS [7] accelerator experiments. The goal of the OPERA experiment [8] is to detect for the first time the appearance in a beam in the atmospheric sector. The path length of the leptons produced in CC interactions is very short (c = 87 m) thus requiring very high spatial resolution. In 2001, the DONUT experiment succeeded in detecting such interactions in Emulsion Cloud Chambers or ECC (Fig. 2).

The detector is exposed to the CERN CNGS beam with an average energy of 17 GeV, well above the lepton production threshold in CC interactions [8]. The rate of prompt is negligible at such energy. It is located in the Gran Sasso underground laboratory (LNGS) at a distance of 730 km from the neutrino source. For the most probable measured values of the oscillation parameters, \( m^2 = 2.4 \times 10^{-3} \text{eV}^2, \sin^2 2\theta = 1.0 \), the fraction of neutrinos having oscillated is about 1.7%. The expected number of detected CC events is about 2.5 for a non-inclusive year of run corresponding to 4.5 \( 10^{19} \) protons on target (pot). See also these proceedings [10].

Figure 2: A tau-neutrino event detected in the DONUT experiment.

3. The OPERA Detector

OPERA is a hybrid detector composed of two identical super-modules. The targets, 1.25 kton in total, are each formed by about 75000 units called hereafter bricks based on the ECC technology. They are assembled into walls interleaved by two orthogonal planes of scintillator strips target trackers (TT) [11] used to
identify the bricks in which the interactions occur. Each target is complemented by a spectrometer that identifies muons and measures their charge and momentum. An overall picture of the detector is shown in Fig. 4 and its detailed description is available in [14].

![Figure 3: ECC, CS, TT.](image)

![Figure 4: The OPERA Detector @ Gran Sasso (1400m underground).](image)

4. Flow of the event analysis

The event analysis is performed in two main steps: location of the neutrino interaction and search for a secondary vertex topology which kinematics is compatible with that of decay.

4.1. Neutrino interactions location

The signal recorded by the electronic detectors, TT and spectrometers, is used to identify the bricks, most often one and up to 3, in which the neutrino interaction is likely to have occurred. Those bricks are extracted from the target by an automaton. The CS are removed from their box, developed and analysed, starting with the most probable brick. The level of background in the CS is negligible; essentially only tracks from the neutrino interaction are recorded. The identification of the brick is thus completed by reading tracks in the CS that are compatible with the electronic data, in which case the brick is disassembled and its ins developed. The tracks found in the CS are extrapolated to the most downstream emulsion, where they are searched for. They are then followed back from the emulsion to the location of the neutrino vertex where they disappear. Finally, emulsion data is taken around this point and the neutrino interaction vertex is reconstructed.

4.2. Decay Search

The four main decay channels of the lepton are given in Table I. Topologically, they are classified as "kink" or "trident" if they have one or three charged daughters. Charm particles have similar lifetime and decay topologies as the lepton. Understanding their detection rate is therefore a direct verification of the expected detection efficiency of the lepton.

Single prong events fall into three categories. For 60% of the events (Fig. 6-bottom), the decay occurs inside the vertex lead plate and the parent traverses no emulsion layer. The decay products are identified by their large impact parameter (IP) with respect to
the primary vertex. For 30% of the events (Fig. 6-top), the parent traverses at least one \( \text{Im} \). In this case, the trajectory of both the parent and the decay product may be reconstructed inside at least one plastic base from data registered in the two emulsion layers, the two micro-tracks, to form a base-track. The candidates are identified by the observation of a kink between both trajectories. For 10% of the events, the parent traverses only one emulsion layer and decays in the \( \text{Im} \) base. There is no base track on the parent trajectory but a single micro-track. Whether the presence of this micro-track will be sufficient to identify the candidates by the observation of a kink or will it be identified by the IP method is under study.

5. Emulsion Technology developed for the OPERA experiment

5.1. The OPERA film

The mass production of the nuclear emulsion \( \text{Im} \)s used for OPERA is the first example of an industrial process. In the past history, nuclear emulsion \( \text{Im} \) or plates were poured by hand. Machine production guarantees homogeneity in thickness and sensitivity unreachable before. An added protective coat allows hand manipulation of the \( \text{Im} \). A new feature of the OPERA \( \text{Im} \) is that tracks already recorded may be erased. This process is called "refreshing".

5.2. Film refreshing

The "refreshing" process was developed to allow erasing the large background of cosmic ray tracks recorded in the \( \text{Im} \)s since their time of fabrication. The signal recorded in nuclear emulsion was known to fade with time at a speed depending on the environment, causing the sensitivity to track detection to progressively decrease. In the OPERA \( \text{Im} \), this fading effect is controllable. By keeping \( \text{Im} \)s at high relative humidity (98%) and high temperature (30°C) for 3 days, more than 99% of the recorded tracks were erased (Fig. 7) while the sensitivity to new recording is not affected. All the \( \text{Im} \)s were refreshed underground in the Tono mine in Japan and then transported to Gran Sasso at sea level. The \( \text{Im} \)s used for the CS require very low background; they were refreshed a second time underground at Gran Sasso.

![Image](image.png)

Figure 7: Film refreshing.

5.3. High speed scanning systems

The scanning area of the OPERA CS measures in \( \text{cm}^2 \); this is more than 100 times larger than for DONUT, the last experiment having used the ECC technique. Therefore high speed scanning systems were developed in both Japan and Europe. The new Japanese scanning system, the S-UTS (Super Ultra Track Selector) is shown on Fig. 8-left. Four systems with a scanning speed of 75 cm\(^2\) per hour and one of 20 cm\(^2\) per hour are operational in Japan. The previous generation operated at speeds of about 1 cm\(^2\) per hour [15]; 5 such systems are used for manual verification and subsidiary tasks. The European scanning machine [16], the ESS (European Scanning System) is shown on Fig. 8-right. It operates at a speed of 20 cm\(^2\) per hour. A total of 33 such systems are currently active for OPERA.

![Image](image.png)

Figure 8: New Scanning Machines.
5.4. Momentum measurement in ECC bricks

The momentum of charged particles can be estimated in ECC bricks by measuring their Multiple Coulomb Scattering [17]. When a particle of charge \( z \), momentum \( p \) and velocity \( c \) traverses a material of depth \( x \) and radiation length \( X_0 \), the distribution of the scattering angle is expressed by a Gaussian, the RMS of which is approximately given by Eq. 1.

\[
\theta = \frac{13.6M \text{ eV}}{cp} \frac{r}{X_0}
\]  

(1)

The measurement of the angle differences in two consecutive films provides the momentum estimation (Fig. 9). The results of a test experiment at KEK are shown in Fig. 10. A brick was exposed to 0.8 GeV/c and 1.5 GeV/c pion beams. The values of the momentum measured by MCs are respectively of 0.79 GeV/c (p/p = 11%) and 1.53 GeV/c (p/p = 16%).

5.5. Electron energy measurement in ECC bricks

Fig. 11 shows the development of electron magnetic showers generated by electrons in an ECC brick. Counting track segments in the shower provides an estimation of the incident electron energy [18]. Fig. 12 shows the result of a test experiment at CERN with 2 GeV and 4 GeV electron beams. There is agreement between the measured and Monte Carlo simulated distributions of the numbers of segments though errors on data are large.

![2GeV electron](image3)

![4GeV electron](image4)

Figure 12: Result of a test experiment at CERN.

5.6. dE/dX measurement in ECC bricks

In nuclear emulsion, the grain density recorded along the track of a charged particle is almost proportional to its energy loss dE/dX (Fig. 13, [19]). ECC bricks have been exposed to 0.4 GeV/c, 0.5 GeV/c, 0.6 GeV/c, 0.74 GeV/c, 0.87 GeV/c, 1.14 GeV/c and 2.0 GeV/c proton and pion beams at KEK. Fig. 14-left illustrates the particle identification capability of the method (pion, proton and deuteron contamination) at 0.87 GeV/c. The relation between the grain...
density and the momentum of the particles is shown Fig. 14-right.

### 6. Status of the 2008 OPERA run

#### 6.1. Location status

Triggers for a total of 1690 events in the target were generated by the TT in time with the CNGS beam arrival. Tables II and III summarize the current status of the events location in the CS and in the bricks after the analysis of the most probable CS indicated by the TT is well advanced. 797 events have been located already in the bricks. For events not found in the CS, the analysis of the next most probable CS has started.

</tr>
</tbody>
</table>

#### 6.2. Decay search status

The search for decay vertices in the events already located is in progress. Fig. 15 shows in red the minimum distance between pairs of tracks with $p > 1$ GeV/c emitted in real neutrino interactions. In blue, it shows the Monte Carlo distribution of the IP with respect to the primary vertex of the daughter particle of leptons decaying in the lead plate of the primary vertex. The minimum distance between all pairs of primary tracks is within 10 m. This demonstrates that the OPERA ECC bricks have enough resolution to identify decay topologies based on the IP.

![Image](305x163 to 531x314)

**Figure 15:** Distribution of minimum distances between pairs of tracks from neutrino interaction (data, $P > 1$ GeV/c).

Some charm decay candidates have already been detected as exemplified in Fig. 16. There are 6 tracks including a $\tau$ at the primary vertex. One of them decays into a $\pi^+$ after a path length of 1330 m. The kink angle is 20.9 mrad and the $P_t$ of the daughter particle is about 460 MeV/c. The beginning of a photon electromagnetic shower is also seen.

7. The 2009 OPERA Run

The OPERA detector suffered no damage following the very strong L’Aquila earthquake of April 2009. The beginning of the run started on June 1 with a delay of a couple of weeks only. A nominal number of 4.5 $10^{19}$ pot is requested from CERN, in which case about 4800 neutrino events would be collected in the OPERA targets by the end of the run and about 2.5 CC interactions would be expected to be detected.

8. Conclusions

The goal of OPERA is to detect $\nu$ oscillation in the appearance mode in the CERN CNGS beam. An innovative nuclear emulsion technology was developed for OPERA. In 2008, triggers for 1690 neutrino events in the targets were recorded. So far, the primary vertices of 797 of these events were located and analyzed in the ECC bricks by a new generation of automatic scanning systems and the work is in progress. First examples of charm decay candidates were found and their kinematical analysis performed. The 2009 run has started on June 1 2009. It should lead to the potential detection of a couple of CC interactions.
