Neutral pion and \( \eta \) meson production
in proton-proton collisions at \( \sqrt{s} = 0.9 \) TeV and \( \sqrt{s} = 7 \) TeV

ALICE Collaboration∗

Abstract

The first measurements of the invariant differential cross sections of inclusive \( \pi^0 \) and \( \eta \) meson production at mid-rapidity in proton-proton collisions at \( \sqrt{s} = 0.9 \) TeV and \( \sqrt{s} = 7 \) TeV are reported. The \( \pi^0 \) measurement covers the ranges \( 0.4 < p_t < 7 \) GeV/c and \( 0.3 < p_t < 25 \) GeV/c for these two energies, respectively. The production of \( \eta \) mesons was measured at \( \sqrt{s} = 7 \) TeV in the range \( 0.4 < p_t < 15 \) GeV/c. Next-to-Leading Order perturbative QCD calculations, which are consistent with the \( \pi^0 \) spectrum at \( \sqrt{s} = 0.9 \) TeV, overestimate those of \( \pi^0 \) and \( \eta \) mesons at \( \sqrt{s} = 7 \) TeV, but agree with the measured \( \eta/\pi^0 \) ratio at \( \sqrt{s} = 7 \) TeV.

∗See Appendix for the list of collaboration members
1 Introduction

Hadron production measurements in proton-proton collisions at the Large Hadron Collider (LHC) \[1\] energies open a new, previously unexplored domain in particle physics, which allows validation of the predictive power of Quantum Chromo Dynamics (QCD) \[2\]. A quantitative description of hard processes is provided by perturbative QCD (pQCD) supplemented with parton distribution functions (PDF) \( f(x) \) and fragmentation functions (FF) \( D(z) \), where \( x \) is the fraction of the proton longitudinal momentum carried by a parton and \( z \) is the ratio of the observed hadron momentum to the final-state parton momentum. Due to the higher collision energy at the LHC, the PDF and FF can be probed at lower values of \( x \) and \( z \) respectively, than in previous experiments. Such measurements can provide further constraints on these functions, which are crucial for pQCD predictions for LHC energies. Furthermore, while pion production at the Relativistic Heavy Ion Collider (RHIC) \[3\] is considered to be dominated by gluon fragmentation only for \( p_t < 5 \sim 8 \) GeV/c \[4, 5\], at LHC energies it should remain dominant for \( p_t < 100 \) GeV/c \[6, 7\]. Theoretical estimates \[6\] suggest that the fraction of pions originating from gluon fragmentation remains above 75% in the \( p_t \) range up to 30 GeV/c. Here, the measurement of the \( \pi^0 \) production cross section at LHC energies provides constraints on the gluon to pion fragmentation \[8\] in a new energy regime. In addition, the strange quark content of the \( \eta \) meson makes the comparison to pQCD relevant for possible differences of fragmentation functions with and without strange quarks \[9\]. Furthermore, the precise measurement of \( \pi^0 \) and \( \eta \) meson spectra over a large \( p_t \) range is a prerequisite for understanding the decay photon (electron) background for a direct photon (charm and beauty) measurement. Finally, a significant fraction of hadrons at low \( p_t \) is produced in pp collisions via soft parton interactions, which cannot be well described within the framework of pQCD. In this kinematic region commonly used event generators like PYTHIA \[10\] or PHOJET \[11\] have to resort to phenomenological models tuned to available experimental data delivered by lower-energy colliders like Sp̅pS, RHIC, and Tevatron \[12\], to adequately describe hadron production. The large increase in center-of-mass energy at the LHC provides the possibility for a stringent test of the extrapolations based on these models.

This paper presents the first measurement of neutral pion and \( \eta \) meson production in proton-proton collisions at center-of-mass energies of \( \sqrt{s} = 0.9 \) TeV and 7 TeV in a wide \( p_t \) range with the ALICE detector \[13\]. The paper is organized as follows: description of the subdetectors used for these measurements, followed by the details about the data sample, as well as about event selection and photon identification, is given in section 2. Section 3 describes the algorithms of neutral meson extraction, methods of production spectra measurement, and shows the systematic uncertainty estimation. Results and their comparison with pQCD calculations are given in section 4.

2 Detector description and event selection

Neutral pions and \( \eta \) mesons are measured in ALICE via the two-photon decay channel. The photons are detected with two methods in two independent subsystems, with the Photon Spectrometer (PHOS) \[14\] and with the photon conversion method (PCM) in the central tracking system employing the Inner Tracking System (ITS) \[15\] and the Time Projection Chamber (TPC) \[16\]. The latter reconstructs and identifies photons converted to \( e^+e^- \) pairs in the material of the inner detectors. The simultaneous measurements with both methods with completely different systematic uncertainties and with momentum resolutions having opposite dependence on momentum provide a consistency check of the final result.

The PHOS detector consists at present of three modules installed at a distance of 4.60 m from the interaction point. PHOS covers the acceptance of \( 260^\circ < \varphi < 320^\circ \) in azimuthal angle and \( |\eta| < 0.13 \) in pseudorapidity. Each module has 3584 detection channels in a matrix of 64 \times 56 cells. Each detection channel consists of a lead tungstate, PbWO\(_4\), crystal of \( 2.2 \times 2.2 \text{ cm}^2 \) cross section and 18 cm length, coupled to an avalanche photo diode and a low-noise charge-sensitive preamplifier. PHOS operates at a temperature of \(-25 \, ^\circ \text{C} \) at which the light yield of the PbWO\(_4\) crystal is increased by about a factor 3
compared to room temperature. PHOS was calibrated in-situ by equalizing mean deposited energies in each channel using events with pp collisions.

The Inner Tracking System (ITS) [13] consists of six layers equipped with Silicon Pixel Detectors (SPD) positioned at a radial distance of 3.9 cm and 7.6 cm, Silicon Drift Detectors (SDD) at 15.0 cm and 23.9 cm, and Silicon Strip Detectors (SSD) at 38.0 cm and 43.0 cm. The two innermost layers cover a pseudorapidity range of $|\eta| < 2$ and $|\eta| < 1.4$, respectively.

The Time Projection Chamber (TPC) [16] is a large ($85 \text{ m}^3$) cylindrical drift detector filled with a Ne/CO$_2$/N$_2$ (85.7/9.5/4.8%) gas mixture. It is the main tracking system of the Central Barrel. For the maximum track length of 159 clusters it covers a pseudorapidity range of $|\eta| < 0.9$ over the full azimuthal angle. In addition, it provides particle identification via the measurement of the specific ionization energy loss ($dE/dx$) with a resolution of 5.5% [16]. The ITS and the TPC are aligned with respect to each other to the level of few hundred $\mu\text{m}$ using cosmic-ray and proton-proton collision data [15].

The event selection was performed with the VZERO detector [17] in addition to the SPD. The VZERO is a forward scintillator hodoscope with two segmented counters located at 3.3 m and $-0.9$ m from the interaction point. They cover the pseudorapidity ranges $2.8 < \eta < 5.1$ and $-3.7 < \eta < -1.7$, respectively.

The proton-proton collision data used in this analysis were collected by the ALICE experiment in 2010 with the minimum bias trigger MB$_{\text{OR}}$ [18]. This trigger required the crossing of two filled bunches and a signal in at least one of the two SPD pixel layers or in one of the VZERO counters. An offline selection based on time and amplitude signals of the VZERO detectors and the SPD was applied to reject beam-induced and noise background [18]. Pileup collision events were identified imposing a criterion based on multiple primary vertices reconstructed with the SPD detector, and removed from the further analysis. The cross sections for the MB$_{\text{OR}}$ trigger have been calculated from other measured cross sections at the same energies with appropriate scaling factors. At $\sqrt{s} = 7$ TeV the cross section for the coincidence between signals in the two VZERO detectors, $\sigma_{\text{MB,AND}}$, was measured in a Van-der-Meer scan [19], and the relative factor $\sigma_{\text{MB,AND}}/\sigma_{\text{MB,OR}} = 0.873$ with negligible error as obtained from data was used. At $\sqrt{s} = 0.9$ TeV the cross section $\sigma_{\text{MB,OR}}$ has been calculated from the inelastic cross section measured in pp collisions at $\sqrt{s} = 0.9$ TeV [20] and relative factor $\sigma_{\text{MB,OR}}/\sigma_{\text{inel}} = 0.91^{+0.03}_{-0.01}$ estimated from Monte Carlo simulations [19].

Table 1 shows the values of the cross section obtained at both energies as well as the integrated luminosity of the total data samples used. In the photon conversion analysis, only events with a reconstructed vertex ($\sim$90% of the total) are inspected, and those events with a longitudinal distance (i.e. along the beam direction) between the position of the primary vertex and the geometrical center of the apparatus larger than 10 cm are discarded. The analysis using PHOS as well as Monte Carlo simulations show that the number of $\pi^0$s in events without a reconstructed vertex is below 1% of the total number of $\pi^0$s.

![Table 1: Cross sections of the reactions and integrated luminosities of the measured data samples for the two beam energies (top), and luminosities used in the different analyses for the 7 TeV data (bottom).](image-url)
To maximize the pion reconstruction efficiency in PHOS, only relatively loose cuts on the clusters (group of crystals with deposited energy and common edges) were used: the cluster energy was required to be above the minimum ionizing energy $E_{\text{cluster}} > 0.3$ GeV and the minimum number of crystals in a cluster was three to reduce the contribution of non-photon clusters.

Candidate track pairs for photon conversions were reconstructed using a secondary vertex (V0) finding algorithm [21]. In order to select photons among all secondary vertices (mainly $\gamma$, $K_0^*$, $\Lambda$ and $\bar{\Lambda}$), electron selection and pion rejection cuts were applied. The main particle identification (PID) selection used the specific energy loss in the TPC ($dE/dx$). The measured $dE/dx$ of electrons was required to lie in the interval $\left[-4\sigma_{dE/dx}, +5\sigma_{dE/dx}\right]$ around the expected value. In addition, pion contamination was further reduced by a cut of $2\sigma$ above the nominal pion $dE/dx$ in the momentum range of 0.25 GeV/c to 3.5 GeV/c and a cut of $0.5\sigma$ at higher momenta. For the $\gamma$ reconstruction constraints on the reconstructed photon mass and on the opening angle between the reconstructed photon momentum vector and the vector joining the collision vertex and the conversion point were applied. These constraints were implemented as a cut on the $\chi^2(\gamma)$ defined using a reconstruction package for fitting decay particles [22]. The photon measurement contains information on the direction which allows to reduce the contamination from secondary neutral pions. With the conversion method a precise $\gamma$-ray tomograph of the ALICE experiment has been obtained [23]. The integrated material budget for $r < 180$ cm and $|\eta| < 0.9$ is $11.4 \pm 0.5 X_0$ as extracted from detailed comparisons between the measured thickness and its implementation in Monte Carlo simulations based on the GEANT 3.21 package using the same simulation runs for the material studies as for the $\pi^0$ measurement. Photon pairs with an opening angle larger than 5 mrad were selected for the meson analysis.

3 Neutral meson reconstruction

Neutral pions and $\eta$ mesons are reconstructed as excess yields, visible as peaks at their respective rest mass, above the combinatorial background in the two-photon invariant mass spectrum. Invariant mass spectra demonstrating the $\pi^0$ and $\eta$ mesons peak in some selected $p_t$ slices are shown in Fig.1 by the histogram. The background is determined by mixing photon pairs from different events and is normalized to the same event background at the right side of the meson peaks. A residual correlated background is further subtracted using a linear or second order polynomial fit. The invariant mass spectrum after subtraction.

![Fig. 1: Invariant mass spectra in selected $p_t$ slices in PCM (left) and PHOS (right) in the $\pi^0$ and $\eta$ meson mass regions. The histogram and the bullets show the data before and after background subtraction, respectively. The curve is a fit to the invariant mass spectrum after background subtraction.](image_url)
background subtraction, depicted by bullets in Fig. 1, was fitted to obtain the \( \pi^0 \) and \( \eta \) peak parameters (a curve). The number of reconstructed \( \pi^0 \)'s (\( \eta \)'s) is obtained in each \( p_t \) bin by integrating the background subtracted peak within 3 standard deviations around the mean value of the \( \pi^0 \) (\( \eta \)) peak position in the case of PHOS. In the PCM measurement the integration windows were chosen to be asymmetric (\( m_{\pi^0} - 0.035 \text{ GeV}/c^2, m_{\pi^0} + 0.010 \text{ GeV}/c^2 \)) and (\( m_{\eta} - 0.047 \text{ GeV}/c^2, m_{\eta} + 0.023 \text{ GeV}/c^2 \)) to take into account the left side tail of the meson peaks due to bremsstrahlung. For the same reason in the case of PCM the full width at half maximum (FWHM) instead of the Gaussian width of the peak was used. We vary the normalization and integration windows to estimate the related systematic uncertainties. The peak position and width from the two analyses compared to Monte Carlo simulations are shown in Fig. 2 as a function of \( p_t \).

![Fig. 2: Reconstructed \( \pi^0 \) peak width (a) and position (b) as a function of \( p_t \) in pp collisions at \( \sqrt{s} = 7 \text{ TeV} \) in PHOS and in the photon conversion method (PCM) compared to Monte Carlo simulations. The horizontal line in (b) indicates the nominal \( \pi^0 \) mass.](image)

The reconstruction efficiency \( \varepsilon \) and acceptance \( A \) are calculated in Monte Carlo simulations tuned to reproduce the detector response. In the PHOS case, the tuning included a 4.5% energy non-linearity observed in real data at \( E < 1 \text{ GeV} \) and not reproduced by the GEANT simulations and an additional 6% channel-by-channel decalibration. In the PCM case, an additional smearing in each momentum component given by \( \sigma = \sqrt{\sigma^2_0 + \sigma^2_1 \cdot p^2} \) with \( \sigma_0 = 0.011 \text{ GeV}/c \) and \( \sigma_1 = 0.007 \) was necessary to reproduce the measured width of the \( \pi^0 \) peak. PYTHIA [10] and PHOJET [11] event generators and single particle simulations were used as input. The small photon conversion probability of about 8.5%, compensated by the large TPC acceptance, translates into \( \varepsilon \cdot A \) of about \( 2 \times 10^{-3} \) at \( p_t > 1 \text{ GeV}/c \) and decreases at lower \( p_t \) due to the decrease of the efficiency of soft electron reconstruction and conversion probability. In the PHOS case, the acceptance \( A \) is zero for \( p_t < 0.4 \text{ GeV}/c \), \( \varepsilon \cdot A \) increases with \( p_t \) and saturates at about \( 2.0 \times 10^{-2} \) at \( p_t > 15 \text{ GeV}/c \). At high \( p_t > 25 \text{ GeV}/c \) the efficiency decreases due to cluster merging.

The invariant differential cross section of \( \pi^0 \) and \( \eta \) meson production were calculated as

\[
E \frac{d^3 \sigma}{dp^3} = \frac{1}{2 \pi N_{\text{events}}} \frac{\sigma_{\text{MB}}}{p_t} \frac{1}{\varepsilon A Br} \frac{N_{\pi^0(\eta)}}{\Delta Y \Delta p_t},
\]

where \( \sigma_{\text{MB}} \) is the interaction cross section for the MB trigger for pp collisions at \( \sqrt{s} = 0.9 \text{ TeV} \) or \( \sqrt{s} = 7 \text{ TeV} \), \( N_{\text{events}} \) is the number of MB events, \( p_t \) is the transverse momentum within the bin to which the cross section has been assigned after the correction for the finite bin width \( \Delta p_t \) (see below), \( Br \) is the branching ratio of the \( \pi^0 \) (\( \eta \)) meson to the two \( \gamma \) decay channel and \( N_{\pi^0(\eta)} \) is the number of reconstructed \( \pi^0 \) (\( \eta \)) mesons in a given \( \Delta Y \) and \( \Delta p_t \) bin. Finally, the invariant cross sections were
corrected for the finite $p_t$ bin width following the prescription in [24], keeping the $y$ values equal to the bin averages and calculating the $p_t$ position at which the differential cross section coincides with the bin average. The Tsallis fit (see below) was used for the correction. Secondary $\pi^0$'s from weak decays or hadronic interactions in the detector material are subtracted using Monte Carlo simulations. The Tsallis fit (see below) was used for the correction. Secondary $\pi^0$'s from weak decays or hadronic interactions in the detector material are subtracted using Monte Carlo simulations.

The contribution from $K^0_S$ decays is scaled using the measured $K^0_S$ spectrum at $\sqrt{s} = 0.9$ TeV [30] or the charged kaon spectra at $\sqrt{s} = 7$ TeV [31]. The measured $\pi^0$ and $\eta$ meson spectra at the center-of-mass energy of $\sqrt{s} = 7$ TeV cover a $p_t$ range from 0.3 to 25 GeV/$c$ and from 0.4 to 15 GeV/$c$, respectively; the $\pi^0$ spectra at $\sqrt{s} = 0.9$ TeV cover a $p_t$ range from 0.4 to 7 GeV/$c$.

![Table 2: Summary of the relative systematic errors for the PHOS and the PCM analyses.](image)

A summary of the systematic uncertainties is shown in Table 2 for two different $p_t$ values. In PHOS, the significant source of systematic errors both at low and high $p_t$ is the raw yield extraction. It was estimated by varying the fitting range and the assumption about the shape of the background around the peak. The uncertainty related to the non-linearity of PHOS which dominates at low $p_t$ was estimated by introducing different non-linearities into the MC simulations under the condition that the simulated $p_t$-dependence of the $\pi^0$ peak position and peak width is still consistent with data. The uncertainties on the calibration and alignment were estimated in Monte Carlo simulations by varying the calibration parameters and the relative module positions within the expected tolerances. The uncertainty related to the pileup event rejection was evaluated in data by estimating the fraction of unidentified pileup events by extrapolating the distance and the number of contributing tracks of found pileup vertices to zero. The uncertainty of the conversion probability was estimated comparing measurements without magnetic field to the standard measurements with magnetic field. In the measurements with converted photons, the main sources of systematic errors are the knowledge of the material budget (dominant at low $p_t$), raw yield extraction, PID, the photon $\chi^2$ cut and reconstruction efficiency. The contribution from the raw yield extraction was estimated by changing the normalization range, the integration window, and the combinatorial background evaluation. The PID, photon $\chi^2(\gamma)$ cut and reconstruction efficiency was estimated by evaluating stability of the results after changing the cut values.

Table 3: Fit parameters of the Tsallis parametrisation \[2\] to the combined invariant production yields of $\pi^0$ and $\eta$ mesons for inelastic events. The uncertainty on the parameter $A$ due to the spectra normalization of $^{+3.2\%}_{-1.1\%}$ and $^{+7.0\%}_{-3.5\%}$ at $\sqrt{s} = 900$ GeV, and 7 TeV respectively, is not included.

4 Results and comparison with pQCD

The combined spectrum is calculated as a weighted average using statistical and systematic errors of the individual analyses \[25\]. The combined production cross sections are shown in Fig. 3(a). The combined spectra including statistical and systematic errors are fitted with the Tsallis function \[26\]

$$E \frac{d^3 \sigma}{dp^3} = \frac{\sigma_{pp}^{\text{INEL}}}{2\pi} A c \cdot \frac{(n-1)(n-2)}{nC nC + m(n-2)} \left(1 + \frac{m - m}{nC}ight)^{-n},$$

where the fit parameters are $A$, $C$ and $n$. $\sigma_{pp}$ is the proton-proton inelastic cross section, $m$ is the meson rest mass and $m_t = \sqrt{m^2 + p_t^2}$ is the transverse mass. The fit parameters are shown in Table 3. The property of the Tsallis function \[2\] is such that the parameter $A$ is equal to the integral of this function over $p_t$ from 0 to infinity, $A = dN/dy$, and thus can be used as an estimation of the total yield at $y = 0$ per inelastic pp collision. The additional uncertainty on the parameter $A$ due to the spectra normalization of $^{+3.2\%}_{-1.1\%}$ and $^{+7.0\%}_{-3.5\%}$ at $\sqrt{s} = 900$ GeV, and 7 TeV respectively, is not included. The found parameters of the Tsallis function for $\pi^0$ production spectrum in pp collisions at $\sqrt{s} = 900$ GeV are in agreement with those for the $\pi^+ + \pi^-$ spectra measured by the ALICE collaboration at the same energy \[27\].

The ratio of the data points of the two methods to the combined fit, shown in Fig. 4, illustrates the consistency between the two measurements.

We compare our results with Next-to-Leading Order (NLO) pQCD calculations using the PDF CTEQ6M5 and DSS $\pi^0$ \[8\], BKK $\pi^0$ \[29\] and AESSS $\eta$ \[9\] NLO fragmentation functions, see Fig. 3(a). The data and NLO predictions are compared via a ratio with the fit to the measured cross section. This is shown in the bottom panels (b), (c) and (d) in Fig. 3. In the NLO calculations the factorization, renormalization and fragmentation scales are chosen to have the same value given by $\mu$. The uncertainty in the inelastic pp cross section is represented by the full boxes at unity. At $\sqrt{s} = 0.9$ TeV the NLO calculations at $\mu = 1 p_t$ describe the measured $\pi^0$ data well, while at $\sqrt{s} = 7$ TeV the higher scale ($\mu = 2 p_t$) and a different set of fragmentation functions are required for a description of the data. However, the latter parameter set does not provide a good description of the low energy data. In any case, the NLO pQCD calculations show a harder slope compared to the measured results. Using the INCNLO program \[28\], we tested different parton distribution functions (CTEQ5M, CTEQ6M, MRS99) and different fragmentation functions (BKK, KKP, DSS) and found a similar result: pQCD predicts harder slopes, and variation of PDFs and FFs does not change the shape, but results mainly in the variation of the absolute cross section. A similar trend is observed for the $\eta$ meson (a higher scale $\mu = 2 p_t$ is required), although the discrepancy is less significant due to the larger error bars and smaller $p_t$ reach.

The ratio $\eta/\pi^0$ is shown in Fig. 5. It has the advantage that systematic uncertainties in the measurement partially cancel. This is also the case for the NLO pQCD calculation, where in particular the influence of the PDF is reduced in the ratio. Here, predictions that failed to reproduce the measured $\pi^0$ and $\eta$ cross section are able to reproduce the $\eta/\pi^0$ ratio.
Fig. 3: a) Differential invariant cross section of $\pi^0$ production in pp collisions at $\sqrt{s} = 7$ TeV (circles) and 0.9 TeV (squares) and of $\eta$ meson production at $\sqrt{s} = 7$ TeV (stars). The lines and the boxes represent the statistical and systematic error of the combined measurement respectively. The uncertainty on the pp cross section is not included. NLO pQCD calculations using the CTEQ6M5 PDF and the DSS (AESS for $\eta$ mesons) FF for three scales $\mu = 0.5 p_t$, $1 p_t$ and $2 p_t$ are shown. Dotted lines in panels b) and c) correspond to the ratios using the BKK FF. Ratio of the NLO calculations to the data parametrisations are shown in panels b), c) and d). The full boxes represent the uncertainty on the pp cross sections.
5 Conclusion

In summary, the invariant differential cross sections for inclusive $\pi^0$ production in pp collisions at $\sqrt{s} = 7$ TeV and 0.9 TeV and for $\eta$ meson production at 7 TeV have been measured in a wide $p_t$ range taking advantage of two independent methods available in the ALICE experiment at the LHC. NLO pQCD calculations cannot provide a consistent description of measured data at both beam energies. State-of-the-art calculations describe the data at 0.9 TeV and 0.2 TeV [32], however this is not the case at 7 TeV, where the calculations overestimate the cross sections and exhibit a different slope compared to the data. Thus, this measurement provides an important input for the tuning of pQCD calculations and represents crucial reference data for the measurement of the nuclear modification factor $R_{AA}$ of the $\pi^0$ production in heavy-ion collisions at the LHC. Furthermore, the NLO predictions for the $\eta$ mesons using the newest fragmentation functions require a value $\mu = 2p_t$ in order to get closer to the experimental results.

6 Acknowledgments

The ALICE collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex.

The ALICE collaboration acknowledges the following funding agencies for their support in building and running the ALICE detector:
