LHCb status and charm physics program

Patrick Spradlin (on behalf of the LHCb collaboration)
Oxford University, Oxford, United Kingdom

LHCb is a dedicated charm physics experiment that will observe the 14 TeV proton (proton collisions at CERN’s Large Hadron Collider (LHC). Construction of the LHCb detector is near completion, and it is fully operational and ready to take data in advance of the projected May 2008 turn-on date for the LHC. The LHCb software trigger will facilitate a dedicated channel for events containing D mesons that will dramatically enhance the statistical reach of LHCb in many charm physics measurements. The LHCb charm physics program is initially focused on mixing and CP violation measurements in two body decay modes of D^0. A much broader program is possible and will be explored as manpower allows. We intend to use both promptly produced charm and secondary charm from B meson decays in measurements. Initial studies have focused on using secondary D^0 mesons from mixing measurements in two body decays. Preliminary Monte Carlo studies indicate that LHCb may obtain a statistical precision of \( \sigma(D^0) = 0.064 \times 10^{-3} \) and \( \sigma(K^0) = 0.57 \times 10^{-3} \) from a time dependent mixing analysis of wrong-sign two body D^0 decays and a statistical precision of \( \sigma(D^0) = 0.15 \times 10^{-3} \) from a ratio of the lifetimes of D^0 decays to the final states K^-K^+ and K^-K^+ and \( \lambda^+ \) in 10\( \times 10^{-4} \) of data.

1. LHCb status

As the dedicated charm physics experiment at CERN’s Large Hadron Collider (LHC), LHCb is designed to optimally exploit the large b production cross-section in the LHC 14 TeV proton (proton collisions for precision measurements of b-hadron properties. Figure 1 shows the layout of the LHCb detector. In high energy hadronic collisions that produce b pairs, the b and D-hadrons are produced principally into the same forward cone, a fact that led to LHCb’s single-arm spectrometer design. The angular acceptance of the detector extends from approximately 10 m rad around the beam axis to 300 m rad in the magnetic bending plane and to 250 m rad in the non-bending plane. Many of the features that make LHCb an excellent B physics laboratory also make LHCb well suited for any charm physics studies at unprecedented levels of precision. The silicon Vertex Locator (VELO) will provide the excellent vertex resolutions necessary for time dependent measurements and an estimated 45 fs proper time resolution for D^0 K^- decay while the D^- mesons are produced in b-hadron decays. The LHCb tracking system will supply precise momentum measurements of two body decay of D^- mesons, an estimated 6 MeV mass resolution for two body decay of D^- mesons. The LHCb Ring Imaging Cherenkov (RICH) detectors will provide excellent K^0 discrimination over a wide momentum range from 2 GeV/c to 100 GeV/c. Finally, the LHCb trigger system will have a high statistics charm stream, described in Section 2, so that the large charm production in LHCb collisions can be exploited for precision measurements.

As of September 2007, construction of the LHCb detector is well advanced with commissioning activities underway for all sub-detectors. LHCb is on schedule to be completed and ready for data taking by the projected LHC turn-on date in May 2008.

2. LHCb trigger and \( D^- \) stream

LHCb will have a two stage trigger: a fast hardware trigger called the Level 0 Trigger (LO) followed by a software High Level Trigger (HLT). Although the triggers are designed to favor b events, the HLT will feature a dedicated D^- stream for selecting charm events at a high rate.

At design operation, LHCb will observe bunch crossings at 40 MHz with a luminosity of \( 2 \times 10^{32} \) cm\(^{-2}\) s\(^{-1}\). The LO trigger is designed to reduce the 40 MHz input rate to approximately 1 MHz while efficiently favoring b events. Using the fact that the decay products of b-hadrons typically have significant transverse momentum, the LO trigger reads data from the calorimeters and the muon detectors to identify quickly individual candidate hadrons, electrons, photons, and muons that have a few GeV of transverse energy or momentum. The

L0 E_T thresholds must be tuned on real data, but, to illustrate the expected scale, current detector studies indicate a trigger threshold for hadrons of E_T > 3.5 GeV.

The HLT software trigger performs an event reconstruction to identify events of specific physics interest, reducing the 1 MHz L0 output/LHT input rate to approximately 2 kHz. The HLT has access to all of the detector information and uses it to reconstruct nonglobal state particle candidates and the locations of the primary proton-proton interactions. These objects are then used in several parallel channels to identify events of specific physical interest. Although the cut information of the HLT channels has yet to be normalized, the HLT will contain a high yield stream for charm events. In the current cut configuration, 300 Hz, 15% of the recorded 2 kHz of LHCb events, are allocated to an inclusive D stream. Table I shows potential yields of some key charm decays in a preliminary configuration of the D stream. These estimates are based on the performance of the HLT on fully simulated LHCb events. LHCb will record at least 50 10^6 fully reconstructed D+! D0 (h h0) candidates per 2 fb-1 (a nominal year of LHCb data at design luminosity), where the D+ originates in a b-hadron decay and h h0 2/3 final state. The subscript on the _f labels it as the tagging “slow” pion. Studies indicate that this HLT configuration also yields a similar number of reconstructed prompt D+ candidates in each mode.

3. D+ event selection

The charm physics program at LHCb is initially focused on measuring CP violation measurements in two-body decays of D0. LHCb note 4 details a preliminary selection of wrong sign (WS) D0 ! K+ decays from D+! D0 , where the D+ originates from a B meson decay. The intent of the selection is to provide a sample of candidates suitable for a time-dependent mixing analysis (see Section 3.1). The performance of the selection on fully simulated LHCb data predicts a yield of approximately 230,000 true WS decays in 10 fb-1 of LHCb data (5 years of nominal LHCb data taking) with a background-to-signal ratio of 1:57 < B/S < 5.28 at the 90% confidence level.

3.1. Selection backgrounds

The primary backgrounds accepted by this selection result from combinations of decays and can be divided into two classes: random slow pion backgrounds where properly reconstructed right-sign D0 ! K+ decays are combined with random pions produced somewhere else in the event to mimic a D decay, and pure combinatorial coincidences where the candidate D0 decay products come from different decay events in the event. These backgrounds will be separated from the signal with the technique of selecting the reconstructed D0 mass (m0) and D+! D0 mass difference (m) distributions.

3.2. D+ decay vertex

In order to perform a time-dependent mixing measurement, both the creation and decay vertices of the D0 must be precisely determined. The D0 decay vertex can be measured from its decay products very precisely in the VELO. Table II shows the results of vertex resolution studies in fully simulated LHCb events. The coordinate system in the table is that defined in Figure 1, with the primary proton-proton collisions along the z axis. The D0 decay vertex can be determined with a resolution of 257 μm along the beam axis. To provide some context for this value, the mean laboratory light distance for a 60 GeV/c D0 (the mean momentum of D0 from D+ from B mesons) is approximately 4 mm.

In contrast, the D+ decay vertex (D0 creation vertex) is poorly determined from its decay products. The small mass difference between the D+ and its decay products leads to a narrow laboratory frame angle between the D0 and D+ momenta. The D+ column in Table II shows that the resolution of the D+ decay vertex estimated from D0 decay products is 423 μm, the same size as the mean laboratory light distance of D0 mesons. The precision of the D+ vertex must be improved by including additional tracks from particles created within the D+ region. For D+ from B decays, this means adding additional charged particles created at the B decay vertex.

In studies of fully simulated events, 63% of B+! D+ X decays in trigger events produce an additional reconstructed charged particle at the B meson decay vertex that can be used to improve the precision of the estimated D0 birth vertex. As shown in Figure 2, using such additional tracks dramatically improves the precision of the estimated D0 production vertex, and, consequently, the measured D0 proper time. The subscript on B part signifies that the parent B is partially reconstructed. Figure 3 shows the dramatic improvement in measured proper time obtained by using the Bpart decay vertex as the D0 production vertex. In these plots, the reconstructed proper time is signed to represent...
4. Charm mixing measurements at LHCb

Mixing observables are commonly expressed in terms of two dimensionless parameters: the mass difference parameter, \( x \), and the full width difference parameter, \( y \), defined by

\[
x = \frac{2(m_1 - m_2)}{1 + 2}; \quad y = \frac{1}{1 + 2};
\]

where the subscripts denote the mass eigenstates of the \( D^0 \bar{D}^0 \) system. Various measurement methods are sensitive to different combinations of these variables, and each of these should be explored with the highest possible precision to gain a full understanding of the charm mixing phenomenon. Preliminary work at LHCb has focused on the measurement of mixing parameters in a time-dependent analysis of two-body \( WS \) decays (Section 4.4 below) and in an analysis of the ratio of two-body lifetimes (Section 4.2 below). However, future plans include multibody mixing measurements (Section 5).

### 4.1. Time dependent WS \( D^0 \rightarrow K^+ \)

The time-dependent analysis of \( WS D^0 \rightarrow K^+ \) decays is one of the long-established methods of searching for \( D^0 \bar{D}^0 \) mixing [3,4,6,8,9]. If \( D^0 \) and \( \bar{D}^0 \) mix, a meson created as a \( D^0 \) may decay to the \( WS \) final state \( K^+ \) either directly, by a doubly Cabibbo suppressed (DCS) decay, or indirectly, by mixing into a \( D^0 \) meson that undergoes a Cabibbo favored (CF) decay. Interference between the two processes leads to a decay time dependence that can be expanded to leading order in the small parameters \( x \) and \( y \) in the absence of CP violation as

\[
r_{WS}(t) = e^{-\frac{\Gamma}{2} t} R_D + \frac{\Gamma}{\sqrt{2} R_M} \cdot \left( x^0 + y^0 \cdot \sin(t) + \frac{1}{2} R_M \cdot \cos(t) \right);\]

where \( R_D \) is the ratio of the DCS decay rate to the CF decay rate, \( R_M = (x^2 + y^2) - 2 = (x^2 + y^2) - 2 \) is the mixing rate, and \( x^0 \) and \( y^0 \) are rotated with respect to the parameters \( x \) and \( y \) by the relative strong phase between the CF and DCS decays:

\[
x^0 = x \cos + y \sin; \quad y^0 = y \cos - x \sin.
\]
Hence, a detailed analysis of the W S D 0 proper time distribution is sensitive to $x^2$ and $y^0$. The strong phase that relates these quantities to the mixing parameters $x$ and $y$ must be measured independently. Since $x^2$ enters the decay time distribution only in $R_1 = (x^2 + y^0)^2$, the values of $x^2$ measured by this method are highly anti-correlated to the values of $y^0$.

Because of the small values of $x$ and $y$, it is only recently that this method has yielded values over 3 from $x^2 = 0$, $y^0 = 0$. The large charm statistics at LHCb should be able to improve significantly this picture. The selection described in Section 3 estimates that a time-dependent WS mixing analysis on 10 fb $^{-1}$ of LHCb data would incorporate approximately 230,000 $D^0$ tagged WS decays from $B$ mesons. The 10 fb $^{-1}$ signal and background yields, the proper time resolution, and the proper time acceptance of this selection were used in a toy Monte Carlo study to estimate the LHCb statistical sensitivity to $x^2$ and $y^0$:

$$\text{stat}(x^2) = 0.064 \quad 10^3; \quad \text{stat}(y^0) = 0.07 \quad 10^3;$$

The toy study verifies the expected large negative correlation between $x^2$ and $y^0$: $\text{Corr}(x^2; y^0) = 0.95$. Figure 3 shows a toy sample from this study.

**4.2. Lifetime ratio**

Just as it does in the $K^0$ and $B^0$ systems, the presence of mixing in the $D^0$ system can lead to different lifetimes for states of different CP content. These differences are related to the mixing parameters $x$ and $y$. In two-body $D^0$ decays, the ratio of the lifetime of decays to the CP-even eigenstate $K^0$ to $K^0$ is,

$$\gamma_{CP} = \frac{(K^0)}{(K^0)}; \quad \gamma_{CP} \approx \frac{1}{2};$$

which is related to the mixing parameters by

$$\gamma_{CP} = y \cos \left( \frac{1}{2} A_M \times \sin \right);$$

where $y$ is a weak phase and $A_M$ parameterizes CP violation in $D^0$ mixing. Decays to the CP-eigenstate $K^+$ may also be used in place of $K^- K^+$ for an independent measurement of $y_{CP}$. The CP-violating parameters $A_M$ and $A_M'$ must be measured independently, but in the no CP violation limit, $A_M = 0$ and the lifetime ratio is a direct measurement of $y_{CP}$.

This two-body lifetime ratio measurement has been carried out at several previous experiments [10, 11, 12, 13] culminating in Belle's recent 32 fb$^{-1}$ measurement of $y_{CP}$ in [14]. LHCb expects to use its statistical advantage over current experiments to improve the precision of the lifetime ratio measurement in $y_{CP}$.

The LHCb statistical sensitivity to $y_{CP}$ has been estimated with a toy Monte Carlo study similar to the WS mixing toy study described in Section 4.2. The selection described in Section 3, with appropriate modifications of the naive state particle identification criteria, yields approximately 8 fb $^{-1}$ of $D^0$ tagged $D^0$ events in the $CP$ observable $LHCB$. The CP-sensitive $S$ and $B$ signal ratios at the selection are $S = 4.8$ for the $K^+ K^-$ mode and $S = 2.6$ for the $K^+ K^-$ mode. Using the estimated $S$ and $B$ yields and signal to background ratio with proper time resolution and acceptance functions determined from fully simulated LHCb events, the estimated statistical precision of $y_{CP}$ is $\text{stat}(y_{CP}) = 0.5 \times 10^3$.

**5. Searches for CP violation at LHCb**

The Standard Model (SM) predicts any CP violation in charm interactions to be very small. Observable CP violation at the level of 1% would be an unambiguous sign of new physics [13]. Each of the mixing measurements perform well at LHCb with CP violation in $D^0$ mesons, in particular the CP eigenstate decays $D^0 \to K^+ K^-$ and $D^0 \to K^+ K^-$. These singly Cabibbo suppressed decays, in which a small CP violation is predicted by the SM, are particularly
sensitive to CP violation enhanced by well-motivated new physics scenarios [15]. Experimental measurements in this channel have steadily reduced the upper limit of CP violation with increasing data set sizes and improved treatment of systematic uncertainties [12, 13]. However, CP violation at the order of 1% has not been ruled out.

With 8 \(10^6\) tagged \(D^0!K^+K^-\) decays and 3 \(10^6\) tagged \(D^0!\bar{K}^+\bar{K}^-\) decays (Section 4.2), LHCB will have the statistical power to search for CP asymmetries to order 0 (0.0004) or below, provided the systematic uncertainties can be controlled to this level.

Charm meson production asymmetries and final state particle detector asymmetries, particularly the detector asymmetry associated with the tagging slow pion, are expected to be the primary sources of systematic uncertainties in CP asymmetry measurements. Methods of measuring the production and detections asymmetries precisely from data are under development. A test advantage may be gained by comparing the asymmetry measurements of related decays. For example, the decays \(D^0!K^+K^-\) and \(D^0!\bar{K}^+\bar{K}^-\) are subject to the same production and slow pion detection asymmetries, so the difference of their measured asymmetries will have a much smaller systematic uncertainty than either asymmetry measured separately. Although this difference will be small, it is an observable that can be measured very precisely, and if found to be significant, can provide evidence of direct CP violation in at least one of the two decay channels.

6. Multi-body channels

LHCb will also investigate the use of charm meson decays to three or more final state hadrons in mixing and CP violation measurements. However, development of multi-hadron charm analyses is less advanced than the two-body D^0 program. For example, a time dependent amplitude analysis of the three body decay \(D^0!K^0S\) is directly sensitive to the mixing parameters \(x\) and \(y\). This decay mode should be efficiently reconstructable at LHCb. Preliminary work is also underway to develop selections for \(D^0\) decays to four hadrons, both for HLT triggering and for analysis. Further development in four body decays will investigate the feasibility of time dependent amplitude analyses for mixing measurements. The technology of four body amplitude analyses is already quite advanced [20].

In four body decays, CP violation searches will include analyses of quantities that are odd under the time reversal operation in addition to complete amplitude analyses of the decays. Although studies are still in their earliest stages, LHCb should be able to reconstruct with acceptable signal-to-background ratios

![Combined Mixing Results](image)

Figure 4: Contours representing the 1, 2, and 3 regions for the toy WS mixing study (ellipses) and for the toy lifetime ratio study (bands). The central values are \(x^2 = 8.4 \times 10^{-3}\) and \(y^2 = 6.4 \times 10^{-3}\), the central value of the toy ratio. For purposes of this plot, it is assumed that \(x^2 = x^2\) and \(y^2 = y^2\).

7. Conclusions

The LHCb trigger will provide LHCb with charm physics data sets of unprecedented statistics and CP violation searches in two body decays \(D^0!h\bar{h}\), but a broader charm physics program is envisaged. Toy Monte Carlo studies indicate that with 10 fb\(^{-1}\) LHCb can achieve a statistical precision of \(y^2 = 0.064 \times 10^{-3}\) and \(y^2 = 0.067 \times 10^{-3}\) with a two body wrong sign mixing analysis, and a statistical precision of \(y^2 = 0.7 \times 10^{-3}\) with a two body lifetime ratio measurement. Figure 4 summarizes the precision studies by showing the intersection of the 1 ellipse in \((x^2, y^2)\), also scaled to 2 and 3, and the toy lifetime ratio 1 band in \(y^2\), also scaled to 2 and 3.
