Superconducting accelerator magnets require sophisticated monitoring and means of protection due to the large energy stored in the magnetic field. Numerical simulations play a crucial role in understanding transient phenomena occurring within the magnet, and can, therefore, help to prevent disruptive consequences. We present a 2-D FEM model for the simulation of electro-thermal transients occurring in superconducting accelerator magnets. The magnetoquasistatic problem is solved with a modified magnetic vector potential formulation, where the cable eddy currents are resolved in terms of their equivalent magnetization. The heat balance equation is then investigated, and the relevant heat sources are discussed. The model implements a two-port component interface and is resolved, as part of an electrical circuit, in a cooperative simulation scheme with a lumped-parameter network.

Index Terms—Superconducting Accelerator Magnet, Quench, Finite Element Method, Equivalent Magnetization, Eddy Currents.

I. INTRODUCTION

CIRCULAR accelerators for high-energy particle physics require intense magnetic fields to control the trajectories of the particle beams. These fields are generated by means of high-field superconducting magnets, which are electrically connected in series, and operated in circuits that contain up to hundreds of elements. It is of paramount importance to ensure a safe management of the stored energy which, if released in an uncontrolled way, could compromise the integrity of the superconducting circuit. This is critical in case of an event such as a quench, where the energy is released as Ohmic losses. Quenches cannot always be prevented, and must be considered among the possible operational scenarios. Generally, dedicated quench detection and protection systems are in place to quickly discharge the stored energy, in order to avoid overheating of the coil. These systems influence both, the quench evolution in the coil and the electrical transient in the rest of the circuit. A careful analysis of the electro-thermal transient is fundamental for the design of both, the magnet and the quench protection system, and for the safe operation of the circuit.

We present a finite-element electro-thermal 2-D model of a superconducting magnet, resolved at the scale of half-turns over which material properties and physics laws are homogenized. The model accounts for the non-linear temperature- and field-dependent material properties and for the induced eddy-currents in the cable, as well as in the coil’s copper wedges. The model consistently resolves the field formulation in presence of iron saturation [2], and dynamic effects in both the coil [3] and the wedges. In particular, the inter-strand eddy currents formulation follows [4], with an extra averaging operator that is discussed in [5,6]. The thermal formulation covers the coil assembly, including structural elements such as insulation foils and wedges, to account for the turn-to-turn and layer-to-layer heat propagation [5,6]. The model has been developed as a modular component of a wider numerical architecture, which implements the concept of cooperative simulation. The aim of the architecture is to resolve the electro-dynamic coupling between the magnet, the protection systems, and the remaining network, leading to consistent simulations.

In this paper, we discuss in detail the electro-thermal formulation, and how it is implemented in the model. Hence we provide a two-port component interface, which is used to co-simulate the model with an external electrical circuit.

II. METHOD

The electro-thermal model combines the magnetic vector potential formulation \( \nabla \times \vec{A} = \vec{B} \) with the heat balance equation. The magnetoquasistatic field solution, fixed with the Coulomb gauge and driven by the current density source \( \vec{J}_c \), determines the magnet’s electrodynamics and the related thermal losses. The eddy-currents’ term \( \sigma \vec{J}_c \vec{A} \), proportional to the conductivity \( \sigma \), is replaced for the cable by an equivalent magnetization factor \( \vec{M}_{cc} \) [1], [2] proportional to the time derivative of the magnetic flux density \( \partial_t \vec{B} \) via an equivalent time constant \( \tau_{loop} \). The cable’s persistent magnetization \( \vec{M}_{pers} \) [1], [8] is considered in \( \vec{M}_{dyn} = \vec{M}_{cc} + \vec{M}_{pers} \), leading the dynamic effects to be consistently included in the constitutive law \( \vec{B} = \nu^{-1}(\vec{H} + \vec{M}_{dyn}) \), where \( \vec{H} \) represents the magnetic field and \( \nu^{-1} \) is the magnetic permeability. The temperature field \( T \) is determined by the balance of the heat \( \rho C_p \partial_t T \) stored in the system, the heat flux \( \nabla \cdot \vec{q} \), and the heat source \( Q \). The contributions to \( Q \) stem from dynamic losses \( Q_{dyn} \) and Ohmic losses \( Q_{ohm} \) in the coil, and eddy current losses \( Q_{eddy} \) in the wedges. The proposed formulation leads, on the 2-D domain \( \Omega \), to the following coupled equations, where \( \vec{A} = (0, 0, A_z) \):

\[
\nabla \times (\nu \nabla \times \vec{A}) = \vec{J}_c + \sigma \partial_t \vec{A} + \nabla \times \vec{M}_{dyn},
\]

\[
C_p \partial_t T + \nabla \cdot \vec{q} = Q,
\]

\[
Q = Q_{dyn} + Q_{eddy} + Q_{ohm}.
\]

The boundary \( \partial \Omega \) is linked to \( \Omega \) through a layer of infinite domain elements \([9]\). Let \( \vec{n} \) be the outward pointing vector; if no symmetry is exploited, the Dirichlet boundary condition \( \vec{n} \times \vec{A} = 0 \) is imposed. The model is driven by an external current \( I_s \) in order to be coupled with the co-simulation algorithm. The current is distributed over the \( n_{ht} \) half-turns as \( \vec{J} = \vec{I}_{ht} \). Through the density function \( \vec{I}_{ht} \), the equivalent currents’ loops at infinity, as in Fig. 1a. Each half-turn \( \Omega_{ht} \) contains \( n_s \) strands of \( d_s \) diameter (see Fig. 1b), made of a composite of superconducting material and copper whose relative volumetric fractions are defined as \( f_{sc} \) and \( f_{cu} \). In the model, the generic half-turn’s surface \( |\Omega_{ht}| = n_s \pi d_s^2 / 4 \) is approximated with a polygon, introducing a discretization error which is compensated through a suitable homogenization density factor \( \kappa_{ht} = |\Omega_{ht}| / |\Omega_{ht}| \). For later use, we define for each half-turn their tilting angle \( \alpha \) and two lines \( \ell_{\omega, \alpha} \), \( \ell_{\eta, \alpha} \) parallel respectively to the wide and narrow edges (see Fig. 1c).

\begin{equation}
\vec{M}_{ISCC} = -\kappa_{ht} \nu \tau_{ISCC, \alpha} \partial_t \vec{B}_{\alpha}.
\end{equation}

The persistent magnetization term \( \vec{M}_{pers} \) accounts for the cable’s persistent eddy currents circulating in the superconducting filaments and it is implemented as in \([1, 6]\), according to the Critical State Model \([13]\), neglecting the hysteretic behavior. The critical current density \( J_{c,ht}(B, T) \) \([1]\), implemented as \([14]\), is homogenized as \( J_{c,ht} = \kappa_{ht} f_{sc} J_c \), leading to

\begin{equation}
\vec{M}_{pers} = -\frac{2}{3\pi} d_t J_{c,ht} \left( 1 - \frac{|\vec{J}_{eddy}|^2}{|\vec{J}_{c,ht}|^2} \right) \vec{a}_B.
\end{equation}

where \( d_t \) represents the superconducting filaments’ diameter, and \( \vec{a}_B = \vec{B} / |\vec{B}| \) is the magnetic flux density versor. \( \vec{M}_{pers} \) decays rapidly with the increase of \( I_s \), being negligible during high-field operations.

The magnet’s structural elements are subjected to eddy currents, which are negligible in the laminated iron yoke and steel collar, but relevant in the copper wedges in the coil assembly. The wedges do not form closed loops at infinity and do not have external leads, so that we require \( \int_{\Omega_{wedge}} (\vec{J}_{eddy} \cdot \vec{n}) \, d\Omega = 0 \).
**C. Heat Balance**

The thermal diffusivity of copper dominates that of the insulation, at cryogenic temperature (10 ≫ 0.05 mm²/s). Therefore, we consider $\Omega_{ht}$ as an isothermal domain, over which the material properties are averaged. The heat diffusion term implements the Fourier Law $\dot{q} = -k\nabla T$ and it accounts for the heat exchanged through both, the insulation layer of each half-turn, and the insulation foil between the inner and outer stack of cables. Due to the aspect ratio of the half-turns’ insulation layer (> 100 on the turn’s wide side), $k$ is redefined as $k_{ht}$, symmetric and anisotropic, to neglect the tangential component of the heat flux. In the implementation, an in-built feature called thin layer avoids to mesh the half-turn’s insulation layer, while the insulation foil is explicitly meshed. The half-turn domains implement a specific heat capacity $\rho_C_{ht}$ which accounts for the superconducting material, the copper stabilizer, the external insulation and for the filling material which impregnates the cable’s voids (see Fig. 1b). Each material contributes with its volumetric fraction $f_i$ to $\rho C_{ht} = \rho_C \sum f_i \rho_C_{p,i} \cdot i$. The heat source $Q$ acting on the coil assembly features three main contributions. The specific losses $Q_{\text{eddy}}$ associated to the eddy currents in the wedges are proportional to the wedges conductivity $\sigma_{\text{wedge}}$, as $Q_{\text{eddy}} = \tilde{J}_{\text{eddy}} \cdot \sigma_{\text{wedge}}^{-1} \tilde{J}_{\text{eddy}}$. The specific losses $Q_{\text{dyn}}$, deposited by the dynamic effects in the coil, are evaluated from the associated variation of the magnetic energy density function $\mathcal{E}$. Losses are determined from $\mathcal{E}$ as $Q_{\text{dyn}} = \hat{M}_{\text{IFCC}} \cdot \partial_t \hat{B} + \hat{M}_{\text{ISC}} \cdot \partial_t \hat{B}_o + \hat{M}_{\text{pers}} \cdot \partial_t \hat{B}$. The contribution $Q_{\text{Ohm}}$ related to the Ohmic losses appears when and where the cable’s working point moves out of the superconducting material’s critical surface $\mathcal{S}$, losing the superconducting state. We model the quench state-transition through a suitable transition-variable $\xi_{ht}$. Joule losses are accounted as $Q_{\text{Ohm}} = \tilde{J}_s \cdot \sigma_{ht}^{-1} \tilde{J}_s$, where the equivalent half-turn resistivity $\sigma_{ht}^{-1}$ is calculated using a reformulation of the Stekly approximation $\mathcal{J}$ for the current sharing regime $\mathcal{K}$, simplifying the extraction of the coil’s equivalent resistance (Sec. II-D). In detail $\sigma_{ht}^{-1}$ is scaled by the $C^1$ class logistic function $\mathcal{L}$ where the tuning coefficients are chosen as $c = 0.5$, $r = 10$, leading to

$$\sigma_{ht}^{-1} = \frac{\xi_{ht}}{\xi_{ht} + f_{\text{Cu}}} \cdot \sigma_{\text{Cu}}^{-1}, \quad \xi_{ht} = \frac{1}{1 + e^{-\left(\frac{x_{ht} - x_{ht,c}}{x_{ht,r}}\right)}},$$

Alternatively to $\mathcal{J}$, one can directly fit the $E = f(J)$ with a logistic function, ensuring a finite amount of energy with respect to the power law $\mathcal{K}$. Nevertheless, in this case the calculation of $\sigma_{ht}^{-1}$ adds an implicit algebraic equation so that $\mathcal{J}$ has been found to be more efficient.

**D. Two-ports component interface**

From the solution we extract two quantities per coil’s unit length: the total resistance $R_c$ and the inductive voltage $U_c$, calculated as the time derivative of the coil’s linked flux. If the average of the vector potential $\hat{A}_{ht}$ over a generic half-turn $\Omega_{ht}$ is introduced, the coil’s equivalent parameters read

$$R_c = \sum_{i=1}^{n_t} \left(\sigma_{ht,i}^{-1} \cdot \Omega_{ht,i}\right), \quad U_c = \sum_{i=1}^{n_t} \left(\hat{\chi}_{ht,i} \cdot \partial_t \hat{A}_{ht,i}\right).$$

Given the turns’ electrical connection order, the definition of the resistive and inductive voltage per turn allows to evaluate the voltage-to-ground distribution along the magnet’s coil.

**III. Results**

The proposed formulation is applied to simulate the Hi-Lumi MQXF quadrupole magnet in a circuit, as a first application to magnets based on Nb$_3$Sn superconducting technology. The two-port component interface (Sec. II-D), combined with the equivalent lumped-parameter representation proposed in $\mathcal{J}$, is used to interface the FEM model with a PSPICE circuit. The chosen value for the circuitual inductance of the magnet is 60 mH $\mathcal{K}$. The circuit simulates a test bench which is arranged as in $\mathcal{J}$, where the formulation has been cross-checked for Nb-Ti magnets. The resistor in parallel with the magnet is equal to 175 mΩ.

The FEM and the circuit models are co-simulated applying the waveform relaxation technique $\mathcal{J}$. The results refer to a simulation scenario called quench-back. The magnet’s nominal operating condition at 1.9 K, 17.8 kA, determines the initial condition of the circuit. Then, the current dynamics and the subsequent field variation induce losses in the coil assembly due to the IFCCs (Fig. 4a) and ISCCs (Fig. 4b) in the cable, and the eddy currents in the wedges (Fig. 4c). Dynamic losses influence the current decay, contributing to dissipate the stored energy, and heat up the coil until superconductivity is lost. While the quench increases the magnet’s...
Eddy-current losses, in W, are to be co-simulated with an external circuit. Assuming in the copper wedges. The thermal formulation includes a thermal model for accelerator magnets. The model accounts for the need of a fast extraction of the stored energy, the quenchback scenario is analyzed, and the magnet’s integrity is assessed.

V. ACKNOWLEDGEMENT

The authors would like to thank K. Król, and J.C. Garnier from CERN for the help provided in the coding of the FEM workflow in Java, and Dr. Sven Friedel and COMSOL Switzerland for continued support and valuable suggestions during the development of the project.

IV. CONCLUSIONS

We successfully developed a 2-D finite-element electro-thermal model for accelerator magnets. The model accounts for the dynamic effects occurring both in the superconducting cable through equivalent magnetization formulations, and in the copper wedges. The thermal formulation includes the coil’s structural elements and accounts for the layer-to-layer propagation. A two-port component interface allows the model to be co-simulated with an external circuit. Assuming

temperature, the coil resistance contributes to an even faster discharge of the current, limiting the deposition of the Ohmic losses (Fig. 4d) which determine the temperature distribution (Fig. 4e). The combination of the resistive and inductive voltage leads to the voltage-to-ground profile presented in Fig. 4f. The model is meshed with 1.3·10³, 2nd-order elements, over which the the monolithically-coupled field equations are discretized and processed by the direct solver PARDISO. The solution required 190 time steps, using a 2nd-order backward differentiation formula. The computational time for a magnet’s quadrant discharge (500 ms) is about 2h, on a standard workstation.
