Abstract. BM@N is the fixed target experiment at the accelerator complex NICA-Nuclotron aimed to study nuclear matter in the relativistic heavy ion collisions. Triple-GEM detectors were identified as appropriate for the BM@N tracking system located inside the analyzing magnet. Seven GEM chambers are integrated into the BM@N experimental setup and data acquisition system. GEM construction, main characteristics and first obtained results of the GEM tracking system performance in the technical run with the deuteron beam are shortly reviewed.

1 Introduction

The BM@N (Baryonic Matter at the Nuclotron) is the first experiment at the accelerator complex of NICA-Nuclotron [1]. Its main purpose is to investigate properties of nuclear matter under extreme density and temperature. The Nuclotron beam energy range corresponds to $\sqrt{s_{NN}} = 2.3 – 3.5$ GeV, which is of great interest for scientific studies, but still poorly investigated.

A scheme of the BM@N experimental setup is shown in Fig. 1. The experiment combines high precision track measurements with time-of-flight information for particle identification and calorimetry for the analysis of the collisions centrality. The magnetic field of the analyzing magnet can be varied up to 1 T to get the optimal detector acceptance and momentum resolution for different reactions and beam energies. The charged particle momentum and multiplicity are measured with the set of Gas Electron Multipliers (GEM) located inside the analyzing magnet and by the Drift Chambers (DCH) situated outside the magnetic field. Double-sided Silicon Micro-strip Sensors (SiMS) are installed between the GEM tracker and the target to improve the track and vertex reconstruction in heavy ion collisions.

Physics measurements will be performed in conditions of high beam intensities up to $10^6$ ions per second in collisions with large multiplicity of charged particles. This requires the use of detectors with the capacity to resolve multiple tracks produced at very high rate. Detectors based on the GEM technology possess all the mentioned characteristics combined with the capability of stable operation in a strong magnetic field. For this reason, two coordinate Triple-GEM detectors were chosen for the central part of the tracking system, which is located inside the analyzing magnet downstream of the target. At present, the GEM tracking system of the BM@N experiment consists of seven detectors: five GEM detectors of the size of $66 \times 41 \text{ cm}^2$ (small GEM detectors) and two GEM detectors of the size of $163 \times 45 \text{ cm}^2$ (big GEM detectors). These detectors were installed into the BM@N set-up for technical runs with the deuteron beam in December 2016 and with the carbon beam in spring 2017.

### 2.1 GEM detector technology and construction

One GEM foil is made of a 50 µm Kapton foil clad on both sides with 5 µm copper electrodes. The GEM foil is optically semi-transparent due to chemical perforation by a large number of holes of about 70 µm diameter, separated by a distance of 140 µm (manufactured by CERN PH Detector Technologies (DT) and Micro-Pattern Technologies (MPT) workshop) [2].
of 2.5 mm, the second transfer gap of 2 mm and the induction gap of 1.5 mm, as it is shown in Fig. 2 (Left).

A two-dimensional projective readout of the electron charge signal is performed on a multilayer readout board with two types of straight parallel metal strips. Their inclination angles to the vertical axis are 0 (X coordinate) and 15 (X’ coordinate) degrees (Fig. 2 Right). There is a hole of 80 mm in diameter in the central region of the big GEM detector in order to install a vacuum beam pipe for heavy ion beam particles. Because of a large multiplicity near the beam line, the readout is divided into the outer and the inner (“hot”) zones. Separate readout of X and X’ strips of each zone is performed by multilayer printed circuit readout board. The rigidity and support of big GEMs is achieved by using two honeycomb plates. Assembly of the BM@N GEM detectors is performed at the CERN PH DT and MPT workshop.

2.2 FEE and DAQ

Front-end electronics is based on the charge sensitive pre-amplifier chip VA162 (IDEAS) [3]. Chips are joined in groups of 4 in one front-end board. The multiplexed data from each board are transmitted through 13 m of twisted pair flat cable to the 12-bit analog-to-digital converter (ADC) readout by the BM@N data acquisition system [4].

2.3 GEM gas gain measurements

To minimize the discharge probability, Ar(90)/C₄H₁₀(10) was selected as a gas mixture for the GEM routine operation within the BM@N experiment, due to its lower, compared to Ar(70)/CO₂(30), values of the electric field in the GEM gas gaps. Measurements of the gas gain as a function of the current in the high voltage divider, designed for the BM@N GEM detectors, were performed using the small GEM detector equipped with the calibrated VA162 FEE irradiated with Fe⁵⁵ radioactive source (Fig. 3). The measurements show, that operational gain of 3·10⁴ for the Ar(90)/C₄H₁₀(10) gas mixture is achieved at a significantly lower value of the divider current compared to the Ar(70)/CO₂(30) gas mixture.

2.4 GEM response uniformity

Studies with 163 × 45 cm² GEM chamber irradiated by ¹⁰⁶Ru radioactive source were performed to measure the response uniformity across the detectors (Fig. 4). Gas gain was measured for 62 points, which were chosen uniformly over the surface of the chamber.
The position of the points is shown on XY plane of the distribution. Gap in 3D plot corresponds to the hole for vacuum beam pipe.

### 3 Beam results

First beam tests of 7 GEM chambers were performed in December of 2016 with the deuteron beam at the Nuclotron accelerator in JINR. The GEM detectors were arranged in 6 planes as it is shown in Fig.1. The left and right parts of the Big GEM detectors were treated as independent detectors. The main goal of the tests was to study the performance of the GEM detectors and the FEE and readout electronics as a part of the BM@N experimental setup. The GEM detectors were filled with the flowed Ar(90)/C$_4$H$_{10}$(10) gas mixture and equipped with the VA162 based electronics. The gas gain was around $3 \times 10^4$ for all the chambers. The measurements were made within the magnetic field varied from 0 up to 0.9 T. The recorded ADC data undergo the pedestal subtraction procedure. The clusters are determined as the groups of adjacent strips with amplitudes of signals above the threshold. For reconstructed clusters, the center of gravity, the width and the total charge are calculated. After applying the alignment procedure for the GEM detector positions, the cluster data were converted into the spatial coordinates of hits. Finally, the tracks of charged particles were reconstructed and track detection efficiency of the GEM chambers was calculated. For the efficiency determination four GEM planes were used as reference detectors and two other were tested. The magnetic field was switched off. The efficiency of the chambers under study was defined from the presence of a cluster with a centre of gravity within ±2 mm of the predicted position.

![Efficiency graph](image)

**Fig. 5.** Left: GEM chamber efficiencies measured in the deuteron beam run in December 2016. Right: The average trajectories of the deuteron beam and the average Lorentz shifts of an electron avalanche in 6 GEM planes measured for three values of the magnetic field.

The efficiencies are presented in Fig.5 (Left) for the vertical X strips, the inclined X’("Y") strips and for the coincidence of the X and X’("Y") strips. The difference in
efficiencies can be explained by the dispersion of FEE amplification factor and by the spatial response non-uniformity of some chambers.

The average shifts of the electron avalanche in the direction perpendicular to the magnetic field (Lorentz shift) were measured from the deviation of hits from the averaged trajectory of the beam as it is illustrated in Fig. 5 (Right). Subsequent GEM planes had opposite directions of the electric field in the detectors. The average positions of hits in 6 GEM planes relative to the average trajectory of the beam are shown in Fig. 6 for different values of the magnetic field. For first two chambers the Lorentz shift value exceeds the average shift by factors 2-3. The reason is in the insufficient rigidity of the support construction of these chambers. That leads to an enlargement of the drift gap due to gas flow, which in turn leads to an increase of the Lorentz shift of the electron avalanche. This construction defect was fixed by installation of an additional support structures on the GEM frames.

Coordinate and momentum resolutions were calculated using data, collected without target and with magnetic field of 0.79 T. Gaussian fit of hit residuals distribution (Fig.6 Left) gives the standard deviation of 0.067, which conform to the Monte-Carlo simulation. Momentum resolution for deuteron beam (9.7 GeV/c) is \(\sim 9\%\) (Fig.6 Right). The resolution for protons from deuteron defragmentation is \(\sim 6\%\).

**Fig. 6.** Left: GEM hit residuals for experimental data. Magnetic field 0.79 T. Right: Momentum resolution for deuteron beam \(\sim 9\%\). Momentum resolution for proton spectators \(\sim 6\%\).

### 4 Conclusions

Seven triple GEM detectors of the BM@N tracker system have been assembled and studied in the deuteron beam of the Nuclotron accelerator. They comprise one third of the central tracking system of the BM@N experiment. Detectors, readout electronics, cables and readout services were successfully integrated into the BM@N experimental setup and tested during the technical run in December 2016. The measured parameters of the GEM detectors are consistent with the design specifications.

This work would not have been possible without the help of V. Spaskov, N. Zamyatin, O. Tarasov, E. Zubarev, A. Smirnov, I. Filippov, N. Azorskiy, V. Sidorenko, S. Piyadin, A. Terletsky, L. Ropelevsky, E. Oliveri.
