Multiplicity dependence of $K^{*}(892)^0$ and $\phi(1020)$ production in pp collisions at $\sqrt{s} = 13$ TeV

ALICE Collaboration

Abstract

Measurements of identified hadrons as a function of the charged-particle multiplicity in pp collisions enable a search for the onset of collective effects in small collision systems. With such measurements, it is possible to study the mechanisms that determine the shapes of hadron transverse momentum ($p_T$) spectra, to search for possible modifications of the yields of short-lived hadronic resonances due to scattering effects in the hadron-gas phase, and to investigate different explanations for the multiplicity evolution of strangeness production provided by phenomenological models. In this paper, these topics are addressed through measurements of the $K^{*}(892)^0$ and $\phi(1020)$ mesons at midrapidity in pp collisions at $\sqrt{s} = 13$ TeV as a function of the charged-particle multiplicity. The results include the $p_T$ spectra, $p_T$-integrated yields, mean transverse momenta, and the ratios of the yields of these resonances to those of longer-lived hadrons. Comparisons with results from other collision systems and energies, as well as predictions from phenomenological models, are also discussed.
1 Introduction

At the LHC, recent studies of p–Pb and pp collisions with high charged-particle multiplicities have shown striking similarities to Pb–Pb collisions. Measurements of azimuthal correlations of particles and anisotropic flow (v$_2$) [1,7] suggest the possibility of collective effects in small collision systems. However, the origins of these effects is not yet fully understood and it remains an open question whether the underlying causes are the same as in large collision systems such as Pb–Pb and Xe–Xe. In order to investigate the origin of these effects, the ALICE Collaboration has measured the $p_T$ spectra and total yields of identified hadrons in p–Pb collisions as a function of the charged-particle multiplicity [8–11], which is used as a measure of the “activity” of the event. The ALICE Collaboration has also studied the multiplicity dependence of light-flavor hadron production in pp collisions for many species: for π$^+$, K$^+$, K$_0^0$, K$^0_S$, K*(892)$^0$, p, φ(1020), Λ, Ξ$^-$, Ω$^-$, and their antiparticles at $\sqrt{s} = 7$ TeV [12,13] and for K$_S^0$, Λ, Ξ$^-$, Ω$^-$, and their antiparticles at $\sqrt{s} = 13$ TeV [14]. This paper reports on an extension of these studies: a measurement of the multiplicity evolution of the production of K*(892)$^0$, K*(892)$^0$, and φ(1020) mesons in pp collisions at $\sqrt{s} = 13$ TeV, the highest energy reached by the LHC in runs 1 and 2. The present study takes advantage of a pp data set recorded during Run 2 of the LHC in 2015 with an integrated luminosity of 0.88 nb$^{-1}$. For the remainder of this paper, the average of K*(892)$^0$ and K*(892)$^0$ will be denoted as K$^{*0}$, while the φ(1020) will be denoted as φ.

The ratios of the yields of strange hadrons to pion yields are observed to be enhanced in nucleus–nucleus (A–A) collisions relative to minimum bias pp collisions [15–17], with the yields in central A–A collisions being well described by statistical thermal models [18–21]. At the LHC, these ratios are observed to increase with the charged-particle multiplicity in pp and p–Pb collisions [8,10,12–14]; the magnitude of the change from low to high multiplicity increases with the strangeness content of the hadron. The ratios in high-multiplicity pp and p–Pb collisions reach the values observed in peripheral Pb–Pb collisions and generally follow similar trends as the multiplicity increases from pp to p–A to A–A collisions. Furthermore, the yields of strange particles are consistent between $\sqrt{s} = 7$ and 13 TeV for similar charged-particle multiplicities. These results suggest that the yields of these hadrons depend primarily on the charged-particle multiplicity and are independent of the collision system and energy.

Several theoretical explanations of the multiplicity evolution of strange-hadron production have been put forward, including canonical suppression, rope hadronization, and core-corona effects. In statistical thermal models of large collision systems, strangeness production is described through the use of a grand canonical ensemble, where strangeness conservation is realized on average across the volume of the system. In the canonical suppression picture, strangeness production in small systems is instead described using a canonical ensemble, requiring the exact local conservation of strangeness within the small volume [13,22,23]. As the size of the system decreases, it makes a transition from the grand-canonical to the canonical description, leading to a decrease in strange-hadron yields with decreasing multiplicity. In the rope-hadronization picture, the larger and denser collision systems form color ropes [24,26], groups of overlapping strings that hadronize with a larger effective string tension. This effect, implemented in models such as DIPSY [27,29], also leads to an increase in the production of strange hadrons with increasing charged-particle multiplicity. Core-corona separation is implemented in a variety of models, including EPOS [30–33] and those described in [34,35]. In these models, the part of the collision system that has high string or parton densities becomes a “core” region that may evolve as a quark–gluon plasma: this is surrounded by a more dilute “corona” for which fragmentation occurs as in the vacuum. Strangeness production is higher in the core region, which makes up a greater fraction of the volume of the larger collision systems. This also results in strangeness enhancement with increasing multiplicity.

The φ meson is a useful probe for the study of strangeness enhancement. The φ contains two strange valence (anti)quarks, but has no net strangeness. Its production should therefore not be canonically suppressed, while the production of hadrons with open strangeness (e.g. kaons or Ξ) may be canonically suppressed [13]. It has, in fact, been rather difficult to describe enhancement of φ-meson production...
in a framework that involves canonical suppression [13]. In contrast, in the rope-hadronization or core-corona interpretations, the yields of φ mesons evolve with multiplicity similarly to particles with open strangeness, leading to an expected increase in the $p_{T}$-integrated $φ/π$ ratio with increasing charged-particle multiplicity. Measurements of φ-meson production as a function of the multiplicity may help to distinguish between the various explanations of strangeness enhancement in small systems.

One of the main motivations for studying resonances like $K^{*0}$ and φ in heavy-ion collisions is to learn more about the properties (temperature and lifetime) of the hadronic phase of the collision. When short-lived resonances (such as $ρ(770)^0$, $K^{*0}$, and $Λ(1520)$) decay, their daughters may re-scatter in the hadronic phase, leading to a reduction in the measurable resonance yields; conversely, resonances may also be regenerated due to quasi-elastic scattering of hadrons through a resonance state [36–41]. Centrality-dependent suppression of $ρ(770)^0$, $K^{*0}$, and $Λ(1520)$ production was observed in Pb–Pb collisions [42–45], and a hint of suppression of $K^{*0}$ suppression was reported for p–Pb collisions [9]. Observations of a similar suppression in high-multiplicity pp collisions (e.g., the $K^{*0}/K$ ratio in pp collisions at $\sqrt{s} = 7$ TeV [12]) might be an indication for a hadronic phase with non-zero lifetime in high-multiplicity pp collisions.

It was observed that the slopes of hadron $p_{T}$ spectra increase with increasing multiplicity in pp and p–Pb collisions [8, 9, 13, 14]. This is at least qualitatively similar to the behavior observed in Pb–Pb collisions, where the observed increase in the slopes can be attributed to a collective expansion of the system; low-$p_T$ particles receive a radial momentum boost, which is greater in higher multiplicity collisions [9, 46]. The color reconnection (CR) mechanism [47–51] can lead to collective flow-like effects, even in small collision systems and in event generators like PYTHIA that do not include QGP formation. The increase in the slopes of the $p_T$ spectra is also mirrored in the trend of the measured mean transverse momenta $⟨p_T⟩$. In contrast to the yields, which evolve along a continuous trend with multiplicity across different collision systems, the $⟨p_T⟩$ values of light-flavor hadrons follow different trends in pp, p–Pb, and Pb–Pb collisions [8, 9, 12, 46], with a faster increase for the smaller systems. The $⟨p_T⟩$ values in the highest multiplicity pp collisions reach, or in some cases exceed, the $⟨p_T⟩$ values observed in central Pb–Pb collisions. The increase in $⟨p_T⟩$ in pp collisions is due to changes in the shapes of the $p_T$ spectra at low $p_T$; for $p_T \gtrsim 4$ GeV/$c$, the shapes of hadron $p_T$ spectra are essentially independent of multiplicity [14, 52].

The results reported here will allow the study of $K^{*0}$ and φ production as functions of both energy and multiplicity in pp collisions. The presented results reach higher values of multiplicity than previously measured in pp collisions and therefore provide important additional information on the production of light-flavor hadrons at LHC energies. This paper is organized as follows. The ALICE detector and the criteria adopted for data selection are described in Section 2. A summary of the data analysis procedure is given in Section 3. The results are presented and discussed in Section 4, followed by a summary and conclusions in Section 5.

2 Event and Track Selection

The ALICE detector is described in detail in [53, 54]. The sub-detectors that are relevant to the analysis described in this paper are the Time Projection Chamber (TPC), the Time-of-Flight detector (TOF), the Inner Tracking System (ITS), the V0 detectors, and the T0 detector. The TPC and ITS are used for tracking and finding the primary vertex, while the TPC and TOF are used for particle identification. The V0 detectors are used for triggering and to define the multiplicity estimator at forward rapidities (pseudorapidity ranges $−3.7 < η < −1.7$ and $2.8 < η < 5.1$). The T0 detector is used for triggering and to provide timing information (including a start signal for the TOF).

The $K^{*0}$ and φ mesons are reconstructed from a sample of $5×10^7$ pp collisions at $\sqrt{s} = 13$ TeV recorded in 2015. The minimum bias trigger required hits in both V0 detectors in coincidence with proton bunches arriving from both directions. Beam-induced background and pile-up events are removed offline; see [14].
the event classes are determined by the number of charged particles at forward rapidities, while the K∗ classes based on the total charge deposited in both V0 detectors (called the “V0M amplitude”). Thus, at least one charged particle in the range |η| > 54° is measured dσ/ch for details. Selected events must also have a primary collision vertex reconstructed with the two innermost layers of the ITS and located within ±10 cm along the beam axis of the nominal center of the ALICE detector. Results in this paper are presented for different event classes corresponding to subdivisions of the “INEL > 0” event class, which is defined as the set of inelastic collisions with at least one charged particle in the range |η| < 1 for the INEL > 0 sample is divided into multiplicity classes based on the total charge deposited in both VO detectors (called the “V0M amplitude”). Thus, the event classes are determined by the number of charged particles at forward rapidities, while the K∗0 and φ yields are measured at midrapidity (|y| < 0.5); this is to avoid correlations between the K∗0 and φ yields and the multiplicity estimator. Particle yields, yield ratios, and mean transverse momenta are plotted for different multiplicity classes (which correspond to different centralities for A–A collisions) as functions of the mean charged-particle multiplicity density at midrapidity ⟨dNch/dη⟩|η|<0.5, where η is the pseudorapidity in the lab frame. As in [14], the various multiplicity classes are denoted using Roman numerals, with class I (X) having the highest (lowest) multiplicity. See Table 1 for the values of ⟨dNch/dη⟩|η|<0.5 measured for each V0M multiplicity class.

Table 1: Charged-particle multiplicity densities at midrapidity ⟨dNch/dη⟩|η|<0.5 for the INEL > 0 class and the various V0M multiplicity classes [14].

| Class | ⟨dNch/dη⟩|η|<0.5 |
|-------|------------|
| INEL > 0 | 6.89±0.11 |
| I | 25.75±0.40 |
| II | 19.83±0.30 |
| III | 16.12±0.24 |
| IV | 13.76±0.21 |
| V | 12.06±0.18 |
| VI | 10.11±0.15 |
| VII | 8.07±0.12 |
| VIII | 6.48±0.10 |
| IX | 4.64±0.07 |
| X | 2.52±0.04 |

[53] for details. Selected events must also have a primary collision vertex reconstructed with the two innermost layers of the ITS and located within ±10 cm along the beam axis of the nominal center of the ALICE detector. Results in this paper are presented for different event classes corresponding to subdivisions of the “INEL > 0” event class, which is defined as the set of inelastic collisions with at least one charged particle in the range |η| < 1 [53]. The INEL > 0 sample is divided into multiplicity classes based on the total charge deposited in both V0 detectors (called the “V0M amplitude”). Thus, the event classes are determined by the number of charged particles at forward rapidities, while the K∗0 and φ yields are measured at midrapidity (|y| < 0.5); this is to avoid correlations between the K∗0 and φ yields and the multiplicity estimator. Particle yields, yield ratios, and mean transverse momenta are plotted for different multiplicity classes (which correspond to different centralities for A–A collisions) as functions of the mean charged-particle multiplicity density at midrapidity ⟨dNch/dη⟩|η|<0.5, where η is the pseudorapidity in the lab frame. As in [14], the various multiplicity classes are denoted using Roman numerals, with class I (X) having the highest (lowest) multiplicity. See Table 1 for the values of ⟨dNch/dη⟩|η|<0.5 measured for each V0M multiplicity class.

Since the K∗0 and φ mesons are short-lived (i.e., their lifetimes are of the order of ~10−23 s and their decay vertices cannot be distinguished from the primary collision vertex), they cannot be measured directly by the detector. Instead, they are reconstructed via their hadronic decays to charged pions and kaons: K∗0 → π±K∓ (branching ratio 66.503 ± 0.014%) and φ → K+K− (branching ratio 49.2 ± 0.5%) [56]. Charged tracks are selected using a set of standard track-quality criteria, described in detail in [9]. Pions and kaons are identified using the specific ionization energy loss dE/dx measured in the TPC and the flight time measured in the TOF. Where the dE/dx resolution of the TPC is denoted as σTPC, pions and kaons are required to have dE/dx values within 2σTPC of the expected value for p > 0.4 GeV/c, within 4σTPC for 0.3 < p < 0.4 GeV/c, and within 6σTPC for p < 0.3 GeV/c (typically, σTPC ~ 5% of the measured dE/dx value). When a pion or kaon track is matched to a hit in the TOF, the time-of-flight value is required to be within 3σTOF of the expected value (σTOF ~ 80 ps) [57]. These event- and track-selection criteria are varied from their default values and the resulting changes in the yields are incorporated into the systematic uncertainties, which are summarized in Table 2.

3 Data Analysis

The K∗0 and φ signals are extracted using the same invariant mass reconstruction method described in [9, 43]. Invariant mass distributions of unlike-charge πK or KK pairs in the same event are reconstructed after particle identification. The combinatorial background is estimated using multiple methods.
In the “like-charge” method, tracks of identical charge from the same event are combined to form pairs. This background is \(2\sqrt{n_{--}n_{++}}\), where \(n_{--}\) and \(n_{++}\) are the number of negative-negative and positive-positive pairs in each invariant mass bin, respectively. In the “mixed-event” method, tracks from one event are combined with oppositely charged tracks from up to 5 other events with similar primary vertex positions and multiplicity percentiles. Specifically, it is required that the longitudinal positions of the primary vertices differ by less than 1 cm and the multiplicity percentiles computed using the V0M amplitude differ by less than 5%. The mixed-event \(\pi K\) (KK) background is normalized so that it has the same integral as the unlike-charge same-event distribution in the invariant mass range \(1.1 < m_{\pi K} < 1.15\) GeV/c\(^2\) (\(1.05 < m_{\text{KK}} < 1.08\) GeV/c\(^2\)). In evaluating the systematic uncertainties, the boundaries of the normalization region for the mixed-event background are varied by \(\sim 100\) MeV/c\(^2\) for the K\(^{+0}\) analysis and \(\sim 10\) MeV/c\(^2\) for \(\phi\).

After subtraction of the combinatorial background, the invariant mass distribution consists of a resonance peak sitting on top of a residual background of correlated pairs. This correlated background contains contributions from jets, resonance decays in which a daughter is misidentified, and decays with more than two daughters. In the analysis of the \(\phi\) meson in pp collisions, the signal-to-background ratio is large and the background is observed to vary slowly in the region of the peak. For these reasons, a third approach is also used to describe the background in the \(\phi\) analysis; the combinatorial background is not subtracted, but is instead parameterized together with the residual background using a function as described below. This has the advantage of providing smaller statistical uncertainties than the other methods.

For \(p_T < 4\) GeV/c, all three methods provide good descriptions of the KK background and give \(\phi\) yields within a few percent of each other. The final \(\phi\) yields for \(p_T < 4\) GeV/c are the averages of those extracted using the three methods of describing the combinatorial background, while the spread among the results for the different methods is incorporated into the systematic uncertainties. As \(p_T\) increases, the yields of hadrons decrease, along with the magnitudes of all of the combinatorial backgrounds studied. The mixed-event background, which lacks any contribution from correlated pairs, is observed to become smaller than the same-event (like- or unlike-charge) combinatorial backgrounds as \(p_T\) increases, eventually tending to 0 for \(p_T\) values higher than the ranges considered here. While the mixed-event background could still be used for the \(\phi\) analysis for \(4 \leq p_T \leq 8\) GeV/c, the two other techniques have smaller statistical fluctuations in this \(p_T\) range. Consequently, the mixed-event technique is not used for the analysis of \(\phi\) for \(p_T > 4\) GeV/c. The mixed-event technique is the primary method used for the extraction of the K\(^{+0}\) yields; variations of the yield due to the use of a like-charge background are covered by the systematic uncertainties. However, for \(p_T < 0.8\) GeV/c in multiplicity class I, the like-charge method is preferred, since it provides a better description of the background. At high \(p_T\), the mixed-event background for the K\(^{+0}\) analysis exhibits the same behavior as for the \(\phi\), but the problems appear at higher \(p_T\) values than for \(\phi\). The mixed-event technique therefore remains the best available option for this K\(^{+0}\) analysis, even at the high end of the \(p_T\) range that was studied.

The invariant mass distributions are fitted with a peak function added to a smooth residual background function. For K\(^{+0}\), the peak is described using a Breit-Wigner function. The mass resolution of the detector for the \(\phi \rightarrow K^- K^+\) channel is of the same order of magnitude as the \(\phi\) width. Therefore, the \(\phi\) peak is described using a Voigt function: a convolution of a Breit-Wigner function and a Gaussian which accounts for the mass resolution of the detector. The K\(^{+0}\) and \(\phi\) width parameters are by default fixed to their vacuum values; to calculate the systematic uncertainties, these parameters are allowed to vary freely and the \(\phi\) resolution parameter is fixed to the values (approximately 1–2 MeV/c\(^2\)) extracted from the Monte Carlo simulations described below. The residual background is parameterized using a second-order polynomial. To evaluate the systematic uncertainties in the K\(^{+0}\) yields, a third-order polynomial is used instead. For the \(\phi\) systematic uncertainties, a first-order polynomial and a function of the form \(A + B m_{\text{KK}} + C \sqrt{m_{\text{KK}}^2 - 2M(K^\pm)}\) are used. Here, \(A, B,\) and \(C\) are free parameters, \(m_{\text{KK}}\) is the kaon-
kaon pair invariant mass, and $M(K^\pm)$ is the mass of the $K^\pm$. The fits are performed in the invariant mass intervals $0.75 < m_{RK} < 1.07$ GeV/c$^2$ for the $K^{0S}$ analysis and $0.995 < m_{KK} < 1.09$ GeV/c$^2$ for the $\phi$. The ranges of the fits are varied by $\sim 20$ MeV/c$^2$ for $K^{0S}$ and $\sim 10$ MeV/c$^2$ for $\phi$; the resulting changes in the yields are included in the systematic uncertainties. Finally, particle yields are extracted by integrating the invariant mass distribution in the peak region ($0.798 < m_{RK} < 0.994$ GeV/c$^2$ for $K^{0S}$ and $1.01 \leq m_{KK} \leq 1.03$ GeV/c$^2$ for $\phi$), subtracting the integral of the residual background function under the peak, and adding the yields in the tails of the peak fit function outside the integration region. The systematic uncertainty arising from “signal-extraction”, as quoted in Table 2, covers the aforementioned variations and adding the yields in the tails of the peak fit function outside the integration region. The systematic uncertainty originating from the procedure used to match track segments in the ITS with tracks in the TPC. The branching ratio correction for the $\phi$ yield introduces a 1% uncertainty, while the corresponding uncertainty for $K^{0S}$ is negligible. Uncertainties in the yields due to uncertainties in the material budget of the detector and the cross sections for hadronic interactions in that material are taken from a previous study [9].

The raw particle yields are corrected for the branching ratios, as well as the acceptance and efficiency of the reconstruction procedure. This correction is calculated using several different event generators (PYTHIA6 Perugia 2011 tune [58], PYTHIA8 Monash 2013 tune [59], and EPOS-LHC [33]), with particles propagated through a simulation of the detector using GEANT3 [60]. No dependence on the generator is observed and the average correction for the three generators is used in order to reduce statistical fluctuations. This correction is of the same order as reported in [9]. A dependence on multiplicity is observed; for $p_T < 3$ GeV/c, the correction increases by $\sim 10\%$ from multiplicity class I to class X. A “signal-loss” correction is also applied, which accounts for $K^{0S}$ and $\phi$ mesons in non-triggered events. This is evaluated using the same simulations as the acceptance and efficiency. To calculate this correction factor, the simulated resonance $p_T$ spectrum before triggering and event selection is divided by the corresponding $p_T$ spectrum after those selections for each multiplicity class. The signal-loss correction typically deviates from unity by $< 1\%$, but can deviate by $\sim 10\%$ at low $p_T$ for the lowest multiplicity class. The PYTHIA6 simulation is used to obtain the central values for this correction, while an uncertainty is evaluated by comparing the central values to those given by PYTHIA8 and EPOS-LHC. Finally, the $p_T$ spectra are normalized by the number of accepted events and corrected as in [14] to account for INEL $>0$ events that do not pass the event-selection criteria. This correction, which is calculated using the PYTHIA6 simulation, is most important (24%) for the lowest multiplicity class and is $< 1\%$ for high-multiplicity collisions (classes I-VIII).

4 Results

The $p_T$ spectra for $K^{0S}$ and $\phi$ in the various multiplicity classes, as well as the ratios of these spectra to the inclusive INEL $>0$ spectrum, are shown in Fig. 1. For $p_T \lesssim 4$ GeV/c the increase in the slopes of the $p_T$ spectra from low to high multiplicity is clearly visible. For higher $p_T$, the spectra in different multiplicity classes all have the same shape, indicating that the processes that change the shape of the $p_T$ spectra in different multiplicity classes are dominant primarily at low $p_T$. A similar behavior was reported for unidentified charged hadrons, $K^0$, $\Lambda$, $\Xi$, and $\Omega$ for the same collision system [14] [52].

The $p_T$-integrated yields $dN/dy$ and mean transverse momenta $\langle p_T \rangle$ are extracted from the $p_T$ spectra in the different multiplicity classes. For each multiplicity class, the $\phi$ yield is extrapolated to the unmeasured region ($p_T < 0.5$ GeV/c) by fitting a Lévy-Tsallis function [61] [62] to the measured $p_T$ spectra. For multiplicity class I (X) the extrapolated $\phi$ yield is 12% (34%) of the total yield. Uncertainties in $dN/dy$ and $\langle p_T \rangle$ are evaluated by varying the fit range and the form of the extrapolation function: Bose-Einstein, Boltzmann, and Boltzmann-Gibbs blast-wave [64] distributions, as well as an exponential in $m_T$ (where $m_T = \sqrt{M^2 + p_T^2}$ and $M$ is the mass of the particle). The uncertainty in the total $\phi$ yield due
Table 2: Sources of systematic uncertainties for the $p_T$ spectra of $K^*$ and $\phi$ reported for low, intermediate, and high $p_T$. When only one value is given for one particle, the uncertainty does not depend on $p_T$. “Signal extraction” includes variations of the combinatorial background, mixed-event normalization region, fitting region, peak shape, and residual background function. The “signal-loss” uncertainty is multiplicity-dependent, hence values are quoted for the highest and lowest multiplicity classes (I and X, respectively). The text “negl.” indicates a negligible uncertainty and “had. int. cross sec.” is short for “hadronic interaction cross section.”

Figure 1: (Color online) $p_T$ spectra of $K^*$ and $\phi$ in pp collisions at $\sqrt{s} = 13$ TeV for different multiplicity classes, scaled by factors as indicated. The lower panels show the ratios of the multiplicity-dependent $p_T$ spectra to the multiplicity-integrated $INEL > 0$ spectra (with both linear and logarithmic vertical scales).
to the extrapolation in class I (X) is 1% (4.4%). The $K^0$ is measured down to $p_T = 0$ and no low-$p_T$ extrapolation is needed. In both cases, the extrapolated yield at high $p_T$ is negligible. The systematic uncertainties on the yield and $\langle p_T \rangle$ are obtained by varying the criteria used in the default analysis. To investigate whether the changes in the yield $dN/dy$ and $\langle p_T \rangle$ are correlated across different multiplicity bins, the effect of changing each criterion is simultaneously evaluated for both the minimum bias event class and each individual multiplicity class. The multiplicity-correlated and uncorrelated components of the systematic uncertainties are separated, with the latter being plotted as shaded boxes in Figs. 2-5.

The mean transverse momenta $\langle p_T \rangle$ for $K^0$ and $\phi$ are shown in Fig. 2 as functions of $\langle dN_{ch}/d\eta \rangle_{|\eta|<0.5}$ and compared with other ALICE measurements and results from model calculations. The $\langle p_T \rangle$ values in pp collisions at $\sqrt{s} = 7$ TeV [13] and 13 TeV follow approximately the same trend. The $\langle p_T \rangle$ values of $K^0$ and $\phi$ rise slightly faster as a function of $\langle dN_{ch}/d\eta \rangle_{|\eta|<0.5}$ in pp collisions than in p–Pb collisions for $\langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \gtrsim 5$; the $\langle p_T \rangle$ values in pp and p–Pb collisions both rise faster than those in Pb–Pb collisions as discussed in [9,13]. The measured $\langle p_T \rangle$ values are compared with five different model calculations: PYTHIA6 (Perugia 2011 tune) [58], PYTHIA8 (Monash 2013 tune, both with and without color reconnection) [59], EPOS-LHC [23], and DIPSY [28]. PYTHIA8 without color reconnection provides an almost constant $\langle p_T \rangle$ as $\langle dN_{ch}/d\eta \rangle_{|\eta|<0.5}$ increases; this is a very different behavior with respect to the trends measured by ALICE and given by the other model calculations. Turning color reconnection on in PYTHIA8 gives better qualitative agreement with the measurements, although the calculation still somewhat underestimates the $\langle p_T \rangle$ values for hadrons containing strange quarks ($K^0_S$, $K^0$, $\phi$, $\Lambda$, $\Xi$, and $\Omega$) [14].

Color reconnection in PYTHIA8 introduces a flow-like effect, resulting in an increase in $\langle p_T \rangle$ values with increasing multiplicity without assuming the formation of a medium that could flow [50]. PYTHIA 6 provides a good description of the $\langle p_T \rangle$ values for $\phi$, but underestimates $\langle p_T \rangle$ for $K^0$. The $\langle p_T \rangle$ values predicted by EPOS-LHC are consistent with the measured values for $\phi$, but slightly below the values for $K^0$. Among the model results obtained for the present work, EPOS-LHC gives the best agreement with the measured data. DIPSY gives a larger increase in $\langle p_T \rangle$ from low to high $\langle dN_{ch}/d\eta \rangle_{|\eta|<0.5}$ than is actually observed; this discrepancy is greater for the $\phi$ and is also observed for other strange hadrons [14].
The values of \( \langle p_T \rangle \) for \( K^0 \) and \( \phi \) are compared with those for \( K^0 \) and strange baryons in the same collision system in Fig. 3. In central A–A collisions, a mass ordering of the \( \langle p_T \rangle \) values is observed; particles with similar masses (e.g., \( K^0 \), p, and \( \phi \)) have similar \( \langle p_T \rangle \) \([9, 46]\). This behavior has been interpreted as evidence that radial flow could be a dominant factor in determining the shapes of hadron \( p_T \) spectra in central A–A collisions. However, this mass ordering breaks down for peripheral Pb–Pb collisions, as well as p–Pb and pp collisions (see Fig. 7 in \([11]\) and measurements reported in \([13, 14]\)).

In pp collisions at \( \sqrt{s} = 13 \text{ TeV} \), the \( \langle p_T \rangle \) values for \( K^0 \) and \( \phi \) are greater than those for the more massive \( \Lambda \) for the same multiplicity classes. The \( \langle p_T \rangle \) values for \( \phi \) even approach those for \( \Xi \), despite the approximately 30\% larger mass of the \( \Xi \). This could be a manifestation of differences between the \( p_T \) spectra of mesons and baryons or different behavior for resonances in comparison to the longer lived particles. In \([13]\), the Boltzmann–Gibbs blast-wave model was used to predict the \( p_T \) spectra of light-flavor hadrons based on a combined fit of \( \pi^\pm \), \( K^\pm \), and (anti)proton \( p_T \) spectra. This study suggested that strange hadrons (\( K^0 \), \( \Lambda \), \( \Xi \), and \( \Omega \)) and other light-flavor hadrons might participate in a common radial flow, even in pp collisions, but that \( K^0 \) and \( \phi \) do not follow this common radial expansion (for details of this study, see \([13]\)). The same behavior could result in the violation of mass ordering for \( \langle p_T \rangle \) seen at \( \sqrt{s} = 13 \text{ TeV} \). A deviation of the \( \langle p_T \rangle \) values of short-lived resonances above the trend for other hadrons could in principle be explained by re-scattering of the resonance-decay daughters during the hadronic phase of the collision, which is expected to be most important at low \( p_T \) \([36]\). However, the strongest re-scattering phenomena occur in central A–A collisions, where no deviation from mass ordering is observed. In addition, such effects would be stronger for the shorter lived \( K^0 \) than for the \( \phi \), which decays predominantly outside the hadronic phase (even in central A–A collisions) and should be minimally affected by re-scattering. On the other hand, the observed violation of mass ordering could be due to differences between baryon and meson \( p_T \) spectra. Baryon-to-meson ratios such as \( p/\pi \) and \( \Lambda/K^0 \) are observed \([8, 13]\) to be enhanced at intermediate \( p_T \) (\( \sim 3 \text{ GeV}/c \)), even in pp and p–Pb collisions, while similar enhancement is not observed in meson-to-meson ratios like K/\( \pi \). Differences between baryons and mesons have also been observed in the \( m_T \) spectra of hadrons measured at RHIC energies \([65, 66]\). For \( m_T \gtrsim 1 \text{ GeV}/c \), meson \( m_T \) spectra follow one common trend, while baryons follow a different, more steeply falling trend as a function of \( m_T \). Such differences between the shapes of baryon and meson spectra may result in mesons having larger \( \langle p_T \rangle \) values than baryons with comparable masses. The breakdown of mass ordering, with \( \langle p_T(p) \rangle < \langle p_T(K^0) \rangle \approx \langle p_T(\Lambda) \rangle < \langle p_T(\phi) \rangle \approx \langle p_T(\Xi) \rangle \), is a common feature of the models shown in Fig. 2. This behavior may be a consequence of hadron production via fragmentation at high \( p_T \) or \( m_T \); meson formation requires only the production of a quark-antiquark pair, while baryon formation requires a diquark-antidiquark pair \([65]\).
The $p_T$-integrated yields of $K^{*0}$ and $\phi$ are shown in Fig. 4 as functions of $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$. For both particles, $dN/dy$ exhibits an approximately linear increase with increasing $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$. Results for pp collisions at $\sqrt{s} = 7$ and 13 TeV and for p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV follow approximately the same trends. This indicates that, for a given multiplicity, $K^{*0}$ and $\phi$ production does not depend on the collision system or energy. Similar results are seen for strange hadrons [14]. The $dN/dy$ values are also compared with those obtained from the same models studied for the discussion of $\langle p_T \rangle$. For the $K^{*0}$, EPOS-LHC and PYTHIA8 without color reconnection give the best descriptions, the other PYTHIA calculations exhibit fair agreement with the measured data, and DIPSY tends to overestimate the $K^{*0}$ yields. The $\phi$ yields tend to be slightly overestimated by EPOS-LHC and slightly underestimated by DIPSY, while the PYTHIA calculations underestimate the $\phi$ yields by about 40%. The selected PYTHIA tunes also underestimate the yields of $\Lambda$, $\Xi$, and $\Omega$ by similar factors [14]. For these baryons, the EPOS-LHC description becomes less accurate with increasing strangeness content; DIPSY describes the $\Lambda$ and $\Xi$ yields well, but understimates the yields of $\Omega$ [14].

The ratios of the $p_T$-integrated particle yields $K^{*0}/K$ and $\phi/K$ are shown in Fig. 5 as functions of $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$. Within their uncertainties the ratios in pp collisions at $\sqrt{s} = 7$ and 13 TeV and in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV are consistent for similar values of $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$. There is a hint of a decrease in $K^{*0}/K$ with increasing $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$ in all three collision systems; for pp collisions at $\sqrt{s} = 13$ TeV the $K^{*0}/K$ ratio in the highest multiplicity class is below the low-multiplicity value at the 2.3 $\sigma$ level. The decrease in $K^{*0}/K$ in central Pb–Pb collisions [9, 43, 44] has been attributed to re-scattering of the $K^{*0}$ decay products in the hadronic phase of the collision [41]. It remains an open question whether a decrease in pp collisions could be caused by the same mechanism. EPOS-LHC provides the best description of the $K^{*0}/K$ ratio in pp collisions at $\sqrt{s} = 13$ TeV. PYTHIA and DIPSY tend to overestimate the ratio for large multiplicities and do not reproduce the apparent decrease with increasing $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$. The $\phi/K$ ratio also follows a similar trend in the three collision systems. It is fairly constant as a function of $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$, although there is an apparent small increase with $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5}$ from the lowest multiplicities up to $\langle dN_{ch}/d\eta \rangle|_{|\eta|<0.5} \approx 400$. EPOS-LHC somewhat
Figure 5: (Color online) Ratios of $p_T$-integrated particle yields $K^*0/K$, $\phi/K$, and $\Xi/\phi$ in pp collisions at $\sqrt{s} = 13$ TeV as functions of $\langle dN_{ch}/d\eta \rangle_{|\eta|<0.5}$ [14]. These measurements are compared with data from $p$–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV [9, 10] and Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [43, 44], as well as results from common event generators [28, 33, 58, 59] and a Canonical Statistical Model calculation [13].

overestimates the $\phi/K$ ratio, but is closer to the measured values than PYTHIA, which significantly underestimates $\phi/K$. While PYTHIA6 and DIPSY underestimate the $\phi/K$ ratio, both results exhibit small increases with increasing multiplicity, which is qualitatively similar to the measured trend. In addition, Fig. 5 also includes the results of a canonical statistical model (CSM) calculation [13] with a chemical freeze-out temperature of 156 MeV; this calculation does not describe the behavior of the measured $\phi/K$ ratio for the $\langle dN_{ch}/d\eta \rangle_{|\eta|<0.5}$ range spanned by the ALICE pp measurements.

In addition to comparing the yields of $\phi$ and kaons, it may be instructive to compare $\Xi$ and $\phi$. These
two particles contain the same number of strange valence (anti)quarks: \( \phi \) is a \( s \bar{s} \) bound state and \( \Xi \) contains two strange valence quarks. However, \( \Xi \) would be subject to canonical suppression, unlike the strangeness-neutral \( \phi \). Figure 5 also shows the \( \Xi/\phi \) ratio in pp, p–Pb, and Pb–Pb collisions. The ratio increases with increasing \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \) for low-multiplicity collisions and is then fairly constant for a wide range of multiplicities: from high-multiplicity pp and p–Pb collisions to central Pb–Pb collisions.

The decrease in \( \Xi/\phi \) with decreasing \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \) for low multiplicities could be interpreted as evidence of canonical suppression in small systems; the canonical statistical model predicts a decrease in the \( \Xi/\phi \) ratio with decreasing \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \) that is qualitatively similar to the measured data. However, canonical suppression would also result in an increase in the \( \phi/K \) ratio with decreasing \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \), which is not observed. Given that \( \Xi \) and K have different numbers of strange valence (anti)quarks, it is expected that \( \Xi \) would be more affected by canonical suppression. It will be interesting to extend the study of the \( \phi/K \) ratio to lower multiplicities to test if there is any increase in this ratio due to canonical suppression of kaon yields. Even in the absence of canonical suppression, the multiplicity evolution of the \( \Xi/\phi \) and \( \phi/K \) ratios suggests that the \( \phi \) meson behaves as if it had between 1 and 2 units of strangeness: i.e., \( \Xi \) is enhanced more than \( \phi \), which is (possibly) enhanced more than K. In addition, there are indications of increases in the \( p/\pi \) and \( \Lambda/K_{S}^{0} \) ratios with increasing \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \), which are qualitatively similar to the increase in \( \Xi/\phi \), but smaller in magnitude. This suggests that baryon-meson differences (e.g., baryon suppression or meson enhancement) might be a contributing factor, but not the only reason, for the low-multiplicity behavior of the \( \Xi/\phi \) ratio. EPOS-LHC, which includes core-corona effects, gives an increasing trend in \( \Xi/\phi \) with increasing \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \), although the values of the ratio and its flattening at high multiplicity are not particularly well described. In contrast, PYTHIA gives a constant or decreasing value of \( \Xi/\phi \) with increasing \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \), which is inconsistent with the observed trend. DIPSY, which includes rope hadronization, describes the \( \Xi/\phi \) ratio over a wide \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \) range, only failing to describe the decrease in the ratio with decreasing multiplicity for the lowest \( \langle dN_{ch}/d\eta \rangle_{|\eta|<0.5} \) values.

The \( p_{T} \) dependence of the particle ratios \( K^{0}/K_{S}^{0} \) and \( \phi/K_{S}^{0} \) is shown in Fig. 6 for low and high multiplicity classes (X and II, respectively). Both ratios increase at low \( p_{T} \) and saturate for \( p_{T} \gtrsim 2.5 \text{ GeV}/c \).
however, for $p_T \lesssim 2.5$ GeV/c the $K^{*0}/K_S^0$ and $\phi/K_S^0$ ratios in the high multiplicity class (X) are less than in the lowest multiplicity class (X). This behavior is qualitatively consistent with observations in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [44], where the $K^{*0}/K$ and $\phi/K$ ratios at low $p_T$ in central collisions are lower compared to pp collisions. The decrease in the low-$p_T$ $K^{*0}/K$ ratio in central Pb–Pb collisions with respect to pp collisions is larger than the decrease in the $\phi/K$ ratio, which could be expected due to the presence of re-scattering effects. To quantify the decrease in these particle ratios in pp collisions at $\sqrt{s} = 13$ TeV, the middle panels of Fig. 6 show the double ratios: the high-multiplicity values divided by the low multiplicity values. The double ratios are consistent with unity for $p_T \gtrsim 2.5$ GeV/c, which suggests a common evolution of the $p_T$ spectra for these three mesons. However for $p_T \lesssim 2.5$ GeV/c, the suppression of the $K^{*0}/K_S^0$ ratio from low to high-multiplicity collisions is greater than the suppression of the $\phi/K_S^0$ ratio. This is quantified in the lower panels of Fig. 6, where the significance of the deviations of the double ratios from unity is shown. For $p_T < 1.2$ GeV/c, the $K^{*0}/K_S^0$ double ratio deviates from unity by 4–6.6 times its standard deviation, while the $\phi/K_S^0$ double ratio deviates from unity at about the 3 $\sigma$ level for $0.6 < p_T < 1.4$ GeV/c. This difference may be a hint of re-scattering in small collision systems.

5 Conclusions

The ALICE Collaboration has reported measurements of the $K^{*0}$ and $\phi$ mesons at midrapidity in pp collisions at $\sqrt{s} = 13$ TeV in multiplicity classes. The results have many qualitative similarities to those reported for longer lived strange hadrons in [14] and may be evidence for collective behavior in small collision systems. The slopes of the $p_T$ spectra of $K^{*0}$ and $\phi$ are observed to increase with increasing multiplicity for $p_T \lesssim 4$ GeV/c, which is qualitatively similar to the collective radial expansion observed in Pb–Pb collisions, but can also be explained through color reconnection. In contrast, the shapes of the $p_T$ spectra are the same for all multiplicity classes at high $p_T$. Both the $p_T$-integrated yields and the mean transverse momenta increase with increasing charged-particle multiplicity at midrapidity, with approximately linear increases for the yields. It appears that, for a given multiplicity value, the yields of these particles are independent of collision system and energy, while the $\langle p_T \rangle$ values follow different trends for different collision systems. The mass ordering of the $\langle p_T \rangle$ values observed in central Pb–Pb collisions is violated in pp collisions, with the $K^{*0}$ and $\phi$ mesons having greater $\langle p_T \rangle$ than baryons with similar masses. The EPOS-LHC model describes the multiplicity dependence of the yields and $\langle p_T \rangle$ fairly well for pp collisions at $\sqrt{s} = 13$ TeV. There are hints that the yields of $K^{*0}$ may be reduced, particularly at low $p_T$ and high multiplicity, by re-scattering of its decay daughters in a short-lived hadron-gas phase in pp collisions; similar behavior is observed in Pb–Pb collisions. The yields of the $\phi$ meson evolve similarly to particles with 1 and 2 units of open strangeness. The $\phi/K$ and $2\phi/3K$ ratios are both fairly constant, exhibiting only slow increases over wide multiplicity ranges, although the $2\phi/K$ ratio decreases with decreasing $\langle dN_{ch}/d\eta \rangle$ at $|\eta| < 0.5$ for the lowest multiplicity pp and p–Pb collisions. In high-multiplicity pp and p–Pb collisions, these ratios reach values observed in central Pb–Pb collisions. This multiplicity evolution is not consistent with simple descriptions of canonical suppression, but is qualitatively described by the DIPSY model, which includes rope hadronization effects. These new measurements of the $\phi$ provide further constraints for theoretical models of strangeness production in small collision systems.

Acknowledgements

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration. The ALICE Collaboration acknowledges the following funding agencies for their support in building and running the ALICE detector: A. I. 117 Technische Universität München, Excellence Cluster 'Universe', Munich, Germany
118 The Henryk Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Cracow, Poland
119 The University of Texas at Austin, Austin, Texas, United States
120 Universidad Autónoma de Sinaloa, Culiacán, Mexico
121 Universidade de São Paulo (USP), São Paulo, Brazil
122 Universidade Estadual de Campinas (UNICAMP), Campinas, Brazil
123 Universidade Federal do ABC, Santo Andre, Brazil
124 University of Cape Town, Cape Town, South Africa
125 University of Houston, Houston, Texas, United States
126 University of Jyväskylä, Jyväskylä, Finland
127 University of Liverpool, Liverpool, United Kingdom
128 University of Science and Technologoy of China, Hefei, China
129 University of South-Eastern Norway, Tonsberg, Norway
130 University of Tennessee, Knoxville, Tennessee, United States
131 University of the Witwatersrand, Johannesburg, South Africa
132 University of Tokyo, Tokyo, Japan
133 University of Tsukuba, Tsukuba, Japan
134 Université Clermont Auvergne, CNRS/IN2P3, LPC, Clermont-Ferrand, France
135 Université de Lyon, Université Lyon 1, CNRS/IN2P3, IPN-Lyon, Villeurbanne, Lyon, France
136 Université de Strasbourg, CNRS, IPHC UMR 7178, F-67000 Strasbourg, France
137 Université Paris-Saclay Centre d’Etudes de Saclay (CEA), IRFU, Département de Physique Nucléaire (DPhN), Saclay, France
138 Università degli Studi di Foggia, Foggia, Italy
139 Università degli Studi di Pavia, Pavia, Italy
140 Università di Brescia, Brescia, Italy
141 Variable Energy Cyclotron Centre, Homi Bhabha National Institute, Kolkata, India
142 Warsaw University of Technology, Warsaw, Poland
143 Wayne State University, Detroit, Michigan, United States
144 Westfälische Wilhelms-Universität Münster, Institut für Kernphysik, Münster, Germany
145 Wigner Research Centre for Physics, Budapest, Hungary
146 Yale University, New Haven, Connecticut, United States
147 Yonsei University, Seoul, Republic of Korea
