1. Introduction

To the best of our knowledge, hot and dense matter is produced in heavy-ion collisions at the Large Hadron Collider (LHC) energies. The system cools down and undergoes a transition to hadron gas. While the particle yields are fixed at the moment when the rate of inelastic collisions becomes negligible (chemical freeze-out), the transverse momentum distributions continue to change until elastic interactions cease (kinetic freeze-out). Studying hadrons and light nuclei containing light flavor and strange quarks is fundamental to better characterize the scenario described above. The yield of light flavor hadrons containing strange quarks is measured to study the dependency of the strangeness enhancement by event activity, colliding system, colliding energy and strangeness content of the particles and to verify if it is present also for particles with hidden strangeness. Production yield of short-lived resonances with lifetimes comparable to that of the fireball is measured to study rescattering and regeneration processes in the dense
hadronic medium. The yield of nuclei and anti-nuclei in heavy-ion collisions provide information about the chemical freeze-out temperature and it is very intriguing to understand how such loosely bound systems can survive the hot fireball.

The ALICE Collaboration performed a systematic study of non-strange hadrons ($\pi^+$, $K^+$, p), single and multi-strange weak decaying hadrons ($K_0^0$, $\Lambda$, $\Xi^-$, $\Omega^-$), short lived resonances ($\rho(770)^0$, $K^*(892)^0$, $\phi(1020)$, $\Sigma^*(1385)^+$, $\Lambda(1520)$, $\Xi(1530)^0$), light nuclei (d, t, $^3$He and $^3$H) and the corresponding antiparticles, in many colliding systems at various energies provided by the LHC$^{1–11}$. The resonances will be referred to only by their commonly used symbol.

2. Results and observations

Particle yields in 0-10% central Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV are compared to predictions from three Statistical Hadronization Models (SHMs), each based on a grand-canonical ensemble, and are shown in the left panel of Figure 1. The models assume hadron production at chemical equilibrium and reproduce most of the measured yields within uncertainties. The estimated chemical freeze-out temperature is about 153 MeV, same as the value obtained in describing the data in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV$^{11,12}$. A remarkable exception is the $K^*$, for which the deficit with respect to the predicted yield can be explained by loss of $K^*$ signal in the hadronic phase. There is also a tension for protons and multi-strange baryons whose explanation requires additional effects (baryon annihilation, interactions in the hadron gas or feed-down from excited hadronic states, etc.)$^{3,6}$. It is notable that the models also reproduce production of nuclei and hyper-nuclei although their binding energies are much smaller than the extracted values of the chemical freeze-out temperature. Overall, SHMs are quite successful and describe yields of production of hadrons which vary over seven orders of magnitude.

One of the most remarkable results established at the LHC is the smooth evolution of particle chemistry from small to large systems as a function of charged particle multiplicity$^1$. The particle yields normalized to charged-pion yield evolve monotonically and continuously as a function of charged particle multiplicity independent of collision energy and system size, as shown in Figure 1 (right). These data also demonstrate, for the first time, the presence of strangeness enhancement in high multiplicity collisions of small systems, the effect being stronger for particles with higher strangeness
content. The original interpretation of this phenomenon, considered as a signature of QGP formation in heavy-ion collisions, is not anymore straightforward. In the strangeness canonical approach, the multiplicity dependence can be explained by requiring local strangeness conservation while the bulk of the particles can still be described in the grand-canonical ensemble. Deviation from this description is present for the $K^{*0}$, while a better description is obtained for $\Xi$ and $\Omega$ applying core-corona corrections. An interesting deviation, is also present for the $\phi$ meson: being a strangeness-neutral particle, a flat multiplicity dependence is predicted, but a trend is observed.

Effect of particle rescattering and regeneration in the hadronic phase can be probed by measuring the yield of hadronic states having a lifetime comparable to the one of the fireball. In this picture the resonance yields in the final state are determined by the resonance yields at chemical freeze-out, their lifetimes, hadronic phase lifetime and by scattering cross sections. Figure 2 (left) shows ratios of the resonance yields to yields of stable hadrons having similar constituent quarks, for a set of particles covering a wide range of lifetimes from 1.3 fm/$c$ for the $\rho^0$ meson up to 46.4 fm/$c$ for the $\phi$ meson. The ratios are suppressed in central heavy-ion collisions for resonances with lifetimes $\tau < 20$ fm/$c$ compared to pp and peripheral heavy-ion collisions. For longer-lived resonances, as the $\phi$, ratios are not suppressed. These results support the existence of a hadronic phase that lives long enough to cause a significant reduction of the reconstructed yields of short lived resonances. Resonance measurements allow for estimates of the hadronic
phase lifetime: 10 fm/$c$ for the most central Pb–Pb collisions and 1-2 fm/$c$ for the most peripheral Pb–Pb collisions. These values are estimated from the EPOS+UrQMD model\textsuperscript{13}.

In order to investigate the behavior of hidden strangeness, the following two ratios have been measured as a function of charged particle multiplicity and are shown in Figure 2 (right): $\Xi(|S|=2)/\phi(|S|=0)$ and $\phi(|S|=0)/K(|S|=1)$. The multiplicity evolution of these two ratios suggests that the $\phi$ meson behaves as if it had between 1 and 2 units of strangeness, so that the $\Xi$ is more enhanced than $\phi$, which is more enhanced than $K$.

Light nuclei are characterised by a low binding energy (EB $\sim$ 1 MeV) compared to the temperature of the chemical freeze-out, (T\textsubscript{ch} $\sim$ 160 MeV). Therefore, in principle one would not expect to observe any nucleus. The experimental results on their production are usually interpreted within two approaches. According to the SHM, (anti-)nuclei are produced at the chemical freeze-out in statistical equilibrium, along with all the other hadrons. As already shown this model nicely predict the yields for d, $^3\Lambda$H and $^3$He in 0-10\% central Pb–Pb collisions. In the coalescence picture, nucleons that are close to each other in phase space after chemical freeze-out can merge and form a nucleus via coalescence. In Figure 3 the coalescence parameter for the deuterons ($B_2$) is shown as a function of charged particle multiplicity in many colliding systems\textsuperscript{2,10}. This is the main observable of the model, related to the probability to form a nucleus via coalescence. $B_2$
is independent of the collision system or the energy, and depends only on the charged particle density. This suggest a common production mechanism that depends only on the system size. In the current state more data and more precise model calculations are needed to discern the production mechanisms of light nuclei.
