Electroweak fits at LEP

E. Lançon

DAPNIA/SPP, CEA-Saclay, 91191 Gif-sur-Yvette Cedex, France

High precision electroweak measurements performed over ten years at LEP and SLC have allowed to constrain the Standard Model of electroweak interactions. The model have been used to predict the mass of the top quark and to set limits on the mass of the Higgs boson.

1. Why electroweak fits?

Electroweak fits have been extensively used at LEP and SLC for testing the Standard Model at the level of its quantum corrections, searching for deviations that may signal the presence of new physics. They have also successively predicted the top quark mass prior to its discovery and recently, allowed to set limit on the Higgs boson mass. Sensitivity to top quark and Higgs boson masses can be inferred from the following example relation:

\[ m_W^2 (1 - \frac{m_W^2}{m_Z^2}) = \frac{\pi \alpha}{\sqrt{2} G_F} (1 + \Delta r) \]

where \( \Delta r \) contains several terms: \( \Delta \alpha \) (due to light fermion masses), a negative term (several \%) proportional to \( m_t^2 \) and a relatively small (below 1\%) term proportional to \( \ln(m_H) \). Therefore, the inferred constraints on \( m_H \) are much weaker than those on \( m_t \).

Before LEP startup, the W and Z boson masses were measured to be \( 80.000 \pm 0.360 \) GeV and \( 91.120 \pm 0.160 \) GeV respectively. These measurements were equivalent to a precision on the weak mixing angle \( \sin^2 \theta_W \) of 3.7\% worse than the direct measurement itself: \( 0.227 \pm 0.006 \) corresponding to 2.6\%. That is the reason why inputs to the Standard Model fits were \( \alpha \), \( G_F \) and \( \sin^2 \theta_W \). In 1995, at the end of LEP-I, the Z boson mass was known with an impressive precision of \( 2.210^{-5} \) hence replacing \( \sin^2 \theta_W \) as input parameter to electroweak fits. The Fermi constant \( G_F \) is determined from the \( \mu \) lifetime, \( G_F = 1.16637(1) \cdot 10^{-5} \text{GeV}^{-2} \) [1]. The relative error of \( G_F \) is comparable to that of \( m_Z \); both errors have negligible effects on the electroweak fit results.

More details can be found in the 2001 summary of the Electroweak Working Group [2].

1.1. The top quark mass

Many of the observables measured at LEP-I and SLC have sensitivity to the top quark mass (typically 20 GeV precision for the measurements of \( R_b \), \( \Gamma_Z \) and \( \sin^2 \theta_W \)), allowing for an impressive precision on the prediction of the top quark mass as the amount of data collected increased, as shown in Figure 1. In 2001, the top quark mass is measured to be \( 174.3 \pm 5.1 \) GeV [3] and the electroweak fit yields \( 181^{+11}_{-9} \) GeV.

1.2. After \( m_t \)?

Once the top quark mass is experimentally known, it is used to further constrain the electroweak fits allowing for predictions of \( m_W \) and of \( m_H \). The first sensitivity curve to the Higgs boson mass (shown as a \( \chi^2 \) curve on Figure 2) was published in the 1994 report of the Electroweak Working Group [4].
Figure 1. Time evolution of the top quark mass derived from electroweak fits, compared to direct searches results.

2. A word about a 3.3$\sigma$ effect

At the time of this note and still for some time, it is difficult to present electroweak fit results without mentioning the so called “3.3$\sigma$” effect.

The asymmetry measurements from LEP and SLD are combined into a single parameter, the effective electroweak mixing angle, $\sin^2\theta_{\text{lept}}^{\text{eff}}$, defined as:

$$\sin^2\theta_{\text{lept}}^{\text{eff}} = \frac{1}{4} \left( 1 - \frac{g_{\nu\ell}}{g_{A\ell}} \right),$$

without making strong model-specific assumptions. In Figure 3 are summarised the different measurements. As it can be seen, the combinations based on the leptonic results plus $A_\ell$(SLD) and on the hadronic forward-backward asymmetries differ by 3.3 standard deviations, mainly caused by the two most precise measurements of $\sin^2\theta_{\text{lept}}^{\text{eff}}$, $A_\ell$ (SLD) dominated by $A_{LR}$, and $A_{0,b}$ (LEP). The averages of the two group of measurements are indicated in Table 1. The average of the six measurements leads to $\sin^2\theta_{\text{lept}}^{\text{eff}} = 0.23152 \pm 0.00017$ with a $\chi^2$ probability of 2.5%. The lepton based average prefers a low $m_H$ value (below 100 GeV), while the hadronic based average prefers a high $m_H$. Before any further considerations, one should keep in mind that $3\sigma$ effects exist in nature. Figure 4 shows the evolution of $\sin^2\theta_{\text{lept}}^{\text{eff}}$ determine at LEP from $A_{0,b}$ (right) and SLD from $A_\ell$ (left) as over seven years. As it can be seen, the significance of the discrepancy does not increase with time as the precision of the measurements does, suggesting a statistical fluctuation nature of the difference.

3. Measurements

On figure 5, the various inputs to the electroweak fits are summarised, also shown the pulls (difference between measurement and fit in units of the total measurement error) of the various measurements. The pulls are derived from the Standard Model fit including all data with the Higgs mass treated as a free parameter. As it can be seen the largest pull (-2.9) if for $A_{0,b}^{c}$ (reflecting the fact the it is the most precise measurement preferring a high $m_H$ value). The pull distribution from all measurements follows a Gaussian law.
4. Theoretical and Parametric Uncertainties

Detailed studies of the theoretical uncertainties in the Standard Model predictions due to missing higher-order electroweak corrections and their interplay with QCD corrections can be found in [5].

The recently calculated complete fermionic two-loop corrections on $m_W$ [6] are currently only used in the determination of the theoretical uncertainty. Their effect on $m_W$ is small compared to the current experimental uncertainty on $m_W$, however, the naive propagation of this new $m_W$ to $\sin^2 \theta_{\text{eff}}^{\text{lept}} = \kappa (1 - m_W^2 / m_Z^2)$, keeps the electroweak form-factor $\kappa$ unmodified, shows a more visible effect as $\sin^2 \theta_{\text{eff}}^{\text{lept}}$ is measured very precisely. Thus the corresponding calculations for $\sin^2 \theta_{\text{eff}}^{\text{lept}}$ (or $\kappa$) and for the partial Z widths are urgently needed; in particular since partial cancellations of these new corrections in the product $\kappa (1 - m_W^2 / m_Z^2) = \sin^2 \theta_{\text{eff}}^{\text{lept}}$ are expected [7].

The use of the new QCD corrections[8] increases the value of $\alpha_S(m_Z^2)$ by 0.001, as expected. The effects of missing higher-order QCD corrections on $\alpha_S(m_Z^2)$ covers missing higher-order electroweak corrections and uncertainties in the interplay of electroweak and QCD corrections and is estimated to be at least 0.002 [9]. The determination of the size of remaining theoretical uncertainties is under continued study.

At present the impact of theoretical uncertainties on the determination of Standard Model parameters from the precise electroweak measurements is small compared to the error due to the uncertainty in the value of $\alpha(m_Z^2)$, which is included in the results.

The uncertainty in $\alpha(m_Z^2)$ arises from the contribution of light quarks to the photon vacuum...

Figure 5. Summary of measurements that enter the electroweak fits together with their pull.

The polarisation \( \Delta \alpha_{\text{had}}(m_Z) \):

\[
\alpha(m_Z^2) = \frac{\alpha(0)}{1 - \Delta \alpha(m_Z^2) - \Delta \alpha_{\text{had}}(m_Z^2) - \Delta \alpha_{\text{top}}(m_Z^2)},
\]

where \( \alpha(0) = 1/137.036 \). The top contribution, \(-0.00007\), depends on the mass of the top quark, and is therefore determined inside the electroweak libraries. The leptonic contribution is calculated to third order [10] to be 0.03150, with negligible uncertainty.

The new evaluation of the hadronic contribution 0.02761 ± 0.0036 which takes into account the recently published results on electron-positron annihilations into hadrons at low centre-of-mass energies by the BES collaboration [11] is used. The uncertainty translates into an error of 0.00013 on the Standard Model prediction of \( \sin^2 \theta_{\text{eff}} \), and errors of 0.2 GeV and 0.1 on the fitted values of \( m_t \) and \( \log(m_H) \), all included in the results presented.

### 5. Fit results

Most observables have sensitivity to the Higgs boson mass as it can be seen in Figure 6. The most sensitive measurements are the asymmetries, \( \sin^2 \theta_{\text{eff}} \), and the W mass. A reduced uncertainty for the value of \( \alpha(m_Z^2) \) would therefore result in an improved constraint on \( \log m_H \) and thus \( m_H \).

![Figure 6](image-url)  

Figure 6. Constraints on \( m_H \) from various observables.

There are also several evaluations of \( \Delta \alpha_{\text{had}}(m_Z^2) \) [12–19] which are more theory-driven. One of the most recent ones (Reference [18]) also includes the new results from BES, yielding 0.02738 ± 0.00020. To show the effects of the uncertainty of \( \alpha(m_Z^2) \), this evaluation of the hadronic vacuum polarisation is also used.
cept the LEP-II and $p\bar{p}$ colliders $m_W$ and $m_t$ results are used. The indirect measurements of $m_W$ and $m_t$ are shown in Figure 7, compared with the direct measurements. Also shown are the Standard Model predictions for Higgs masses between 114 and 1000 GeV. As can be seen in the figure, the indirect and direct measurements of $m_W$ and $m_t$ are in good agreement, and both sets prefer a low value of the Higgs mass.

From a fit to all data except $m_W$, the best indirect determination of $m_W$ is obtained. The indirect determination of W boson mass $80.373 \pm 0.023$ GeV is in agreement with the combination of direct measurements from LEP-II and $p\bar{p}$ colliders [22] of $m_W = 80.451 \pm 0.033$ GeV.

Similarly, the indirect determination of the top quark mass: $m_t = 181^{+9}_{-11}$ GeV, is in very good agreement with the direct measurement of $m_t = 174.3 \pm 5.1$ GeV.

Finally, the best constraints on $m_H$ are obtained when all data are used in the fit. In Figure 8 the observed value of $\Delta \chi^2 = \chi^2 - \chi^2_{\text{min}}$ as a function of $m_H$ is plotted for the fit including all data. The $\chi^2$ per degree of freedom of the fit is 23/15 corresponding to a probability of 8%. The solid curve is the result using ZFITTER. The result is $\log(m_H/\text{GeV}) = 1.94 \pm 0.21$, corresponding to $m_H = 88^{+53}_{-35}$ GeV. The shaded band represents the uncertainty due to uncalculated higher-order corrections, as estimated by ZFITTER and TOPAZ0. Compared to previous analyses, its width is enlarged towards lower Higgs-boson masses due to the effects of the complete fermionic two-loop calculation of $m_W$ discussed above. The 95% confidence level upper limit on $m_H$ (taking the band into account) is 196 GeV. The lower limit on $m_H$ of approximately 114 GeV obtained from direct searches[23] is not used.

![Figure 7](image-url) Figure 7. The comparison of the indirect measurements of $m_W$ and $m_t$ (solid contour) and the direct measurements (dashed contour). In both cases the 68% CL contours are plotted. Also shown is the Standard Model relationship for the masses as a function of the Higgs mass.

![Figure 8](image-url) Figure 8. $\Delta \chi^2 = \chi^2 - \chi^2_{\text{min}}$ vs. $m_H$ curve. The line is the result of the fit using all data; the band represents an estimate of the theoretical error due to missing higher order corrections. The vertical band shows the 95% CL exclusion limit on $m_H$ from the direct search.
in the determination of this limit. Also shown is the result (dashed curve) obtained when using \( \Delta \alpha_{\text{had}}^{(5)}(m_Z^2) \) of Reference [18]. That fit results in \( \log(m_H/\text{GeV}) = 2.03 \pm 0.19 \) corresponding to \( m_H = 106^{+57}_{-38} \) GeV and an upper limit on \( m_H \) of approximately 222 GeV at 95% confidence level.

The variation of the upper limit on \( m_H \) against experimental parametric errors is tested in Figure 9, where \( \Delta \chi^2 \) curves corresponding to one sigma variation of \( \Delta \alpha_{\text{had}}^{(5)}(m_Z^2) \) and \( m_t \) are plotted. Although the position of the minimum changes because of the relative changes of the different measurement in the fit, the upper limit on \( m_H \) does not increase above 300 GeV.

![Figure 9](image)

\( \Delta \chi^2 \) for one sigma change of \( \Delta \alpha_{\text{had}}^{(5)}(m_Z^2) \) or \( m_t \) and both.

6. Conclusions and Perspectives

The measurement of \( m_W \) at LEP-II is likely to reach a precision of \( \approx 25 \text{ MeV} \), not too far from the uncertainty on the prediction obtained via the radiative corrections of the \( Z \) data, providing a further important test of the Standard Model. As the LEP energy final value is not yet known, the absolute \( m_W \) mass value from LEP might change. However to further, significantly, constrain \( m_H \) a more accurate measurement of \( m_t \) is mandatory. A precision of 2 GeV is likely to be obtained at FERMILAB run II. Figure 10 shows the \( \Delta \chi^2 \) curves that would be obtained with such precisions, without any change in central values of measurements. A precision of about 20 GeV on \( m_H \) is reachable.

![Figure 10](image)

\( \Delta \chi^2 \) curves for a precision of 25 MeV on \( m_W \) and 2 GeV on \( m_t \). Central values of \( m_W \) and \( m_t \) are kept unchanged.

Figure 11 shows the evolution of both the lower limit on the Higgs boson mass from direct searches (hatched area) and the upper limit from electroweak fits (dashed area) as a function of time. The gap is not closed, a slightly longer run for LEP with a bit higher energy might have closed it.

Electroweak fits from LEP and SLC data have allowed to test the internal consistency of the Standard Model with great precision, three to five times better than anticipated. The top quark mass was predicted several years before it has been discovered. The measurements led to the prediction of a relatively light Higgs boson (around 100 GeV), with the same precision (\( \approx 50\% \)) as on the top quark mass before LEP and SLC startup.
Figure 11. Variation over seven years of the lower limit on the Higgs boson mass from direct searches (dashed area) compared to the upper limit derived from electroweak fits (shaded area).
