MULTI-TURN EXTRACTION AND INJECTION BY MEANS OF ADIABATIC CAPTURE IN STABLE ISLANDS OF PHASE SPACE

R. Cappi and M. Giovannozzi

Abstract

Recently a novel approach has been proposed aimed at performing multi-turn extraction from a circular machine. Such a technique consists of splitting the beam by means of stable islands created in transverse phase space by magnetic elements creating nonlinear fields, such as sextupoles and octupoles. Provided a slow time-variation of the linear tune is applied, adiabatic with respect to the betatron motion, the islands can be moved in phase space and eventually charged particles may be trapped inside the stable structures. This generates a certain number of well-separated beamlets. Originally, this principle was successfully tested using a fourth-order resonance. In this paper the approach is generalised by considering other type of resonances as well as the possibility of performing multiple multi-turn extractions. The results of numerical simulations are presented and described in detail. Of course, by time-reversal, the proposed approach could be used also for multi-turn injection.

1 INTRODUCTION

A special technique is normally used to fill the CERN Super Proton Synchrotron (SPS) with a high-intensity proton beam delivered by the Proton Synchrotron (PS), the so-called Continuous Transfer (CT) [1]. The beam is sliced using an electrostatic septum: by properly defining a closed orbit perturbation and by setting the horizontal tune equal to $Q_H = 6.25$ the beam is extracted from the PS over five consecutive turns. A continuous ribbon four-turn long is extracted first, while the remaining central core is extracted last thus generating a proton spill five-turn long (see Refs. [1, 2] for more details). Such a multi-turn extraction might not be the best choice for the planned CERN Neutrino to Gran Sasso (CNGS) proton beam [3], especially in case of an intensity upgrade [4], due to the intrinsic losses, of the order of $15 - 20\%$ of the overall proton intensity, onto the electrostatic septum as well as the poor betatron matching of the resulting slices. Detailed analytical computations of the expected betatron mismatch and potential emittance blow-up at injection into the SPS have been reported in Ref. [2].

An alternative method was proposed [5, 6]. The beam is split in the transverse horizontal phase space by trapping particles inside stable islands created by sextupole and octupole magnets. The tune has to be varied in order to create the appropriate phase space topology [5]. The principle consists in sweeping through the chosen resonance so to change the phase space topology from a situation where no islands are present, to a final stage where stable islands are created. During the resonance crossing stage, small islands appear around the origin of phase space occupied by the beam. Therefore, particles can get trapped inside the stable structures, thus generating a number of beamlets proportional to the resonance order. Such beamlets are eventually transported towards higher amplitudes by keeping changing the tune so to increase their separation and to produce regions emptied of particles in between the beamlets [5]. At this stage, it is possible to induce a distortion of the beam closed orbit so to jump a septum, whose blade will be located in the empty space between the beamlets. Therefore, the beam is extracted over many turns without the need of any intercepting device to split it, thus reducing the losses. In addition, as it was shown in Ref. [2], the betatron mismatch is greatly improved with respect to, e.g., the present CT extraction. It is important to stress that this approach is not affected by particle de-trapping, typical of modulational diffusion (see Ref. [7] for a general overview of the problem) as the tune variation is not periodic.

For the specific CERN application the fourth-order resonance was studied [5]. However, following the encouraging results, numerical simulations were performed also for the third-order resonance [6] showing the validity of the method even in that case.

Preliminary experimental results obtained during the 2002 run of the PS machine allowed observing the trapping process into stable islands of phase space in real machines [8]. In this paper the latest results of numerical simulations are presented, showing how to perform multi-turn extraction over a small number of turns, from two to six, using adiabatic trapping inside a properly chosen resonance. Other possibilities are also explored, such as the option of performing multiple multi-turn extractions.

The plan of the paper is the following: in section 2 the model used in the numerical simulations is presented and discussed, while in section 3 the results of the numerical simulations for various resonances, ranging from second order (section 3.1) to fifth order (section 3.4), are presented, with particular emphasis for the fourth-order resonance (section 3.3) in view of its potential applications to the CERN PS machine. In section 4 results concerning multiple multi-turn extraction are presented and some conclusions are drawn in section 5. Finally, two appendices report in detail the way the one-turn transfer
map is computed (Appendix A) and some results concerning fixed points of symplectic maps (Appendix B) relevant for the model used for the two-turn extraction.

2 NUMERICAL MODEL

The computation of the one-turn transfer map depends on the assumption made for the structure of the circular machine under study. By assuming that the magnets generating the nonlinear magnetic fields are located at the same place in the ring, and that they effect on the beam dynamics is represented using the single-kick approximation [9], then the one-turn transfer map is a Hénon-like [10] 4D polynomial map, which can be expressed as \( \hat{X}_{n+1} = M_n(\hat{X}_n) \):

\[
\begin{pmatrix}
\hat{X} \\
\hat{X}' \\
\hat{Y} \\
\hat{Y}'
\end{pmatrix}_{n+1} = R(\omega_x, \omega_y)
\begin{pmatrix}
\hat{X} \\
\hat{X}' + \hat{X}^2 - \chi \hat{Y}^2 + \kappa \left( \hat{X}^3 - 3\chi \hat{X} \hat{Y}^2 \right) \\
\hat{Y} \\
\hat{Y}' + -2 \chi \hat{X} \hat{Y} - \kappa \left( \chi^2 \hat{Y}^3 - 3\chi \hat{X}^2 \hat{Y} \right)
\end{pmatrix}_n.
\]

The components of the vector \((\hat{X}, \hat{X}', \hat{Y}, \hat{Y}')\) are dimensionless coordinates allowing to set the coefficient of the quadratic term of the map (1) to one. More details on the relations between physical, Courant-Snyder [11], and coordinates used here can be found in Appendix A.

The manipulations required to capture the beam inside stable islands are performed in the horizontal plane, only. This means that, provided the vertical tune is chosen carefully so to avoid low-order resonances, the vertical degree of freedom can be safely neglected in the numerical simulations and the map (1) can be replaced by the 2D one-turn map given by

\[
\begin{pmatrix}
\hat{X} \\
\hat{X}'
\end{pmatrix}_{n+1} = R(\omega_x) \begin{pmatrix}
\hat{X} \\
\hat{X}' + \hat{X}^2 + \kappa \hat{X}^3
\end{pmatrix}_n.
\]

This approach is used for most of the multi-turn extraction schemes presented in this paper, unless for the special case of the five-turn extraction, where 4D simulations have been performed and they confirm that the neglected vertical degree of freedom does not alter the result obtained with the 2D map (2).

The case of two-turn extraction deserves special considerations. In fact, 2D one-turn transfer maps of the form (2) do not have any fixed point of order two. This is a consequence of the symmetry induced by locating the sextupole and octupole in the same section of the machine (the reason for this is discussed in detail in Appendix B). If this condition is broken, one can find a class of maps with fixed points, and stable islands, of period two. This is the case of the following maps

\[
\begin{pmatrix}
\hat{X} \\
\hat{X}'
\end{pmatrix}_{n+1} = R(\omega_x) \circ K_{\text{sextupole}} \circ R(\bar{\omega}) \circ K_{\text{octupole}}(\hat{X}, \hat{X}')_n.
\]

The polynomial maps \(K_{\text{sextupole}}, K_{\text{octupole}}\) represent sextupolar and octupolar kicks, respectively, of the form

\[
K_{\text{sextupole}}(\hat{X}, \hat{X}') = \begin{pmatrix}
\hat{X} \\
\hat{X}' + \hat{X}^2
\end{pmatrix}, \\
K_{\text{octupole}}(\hat{X}, \hat{X}') = \begin{pmatrix}
\hat{X} \\
\hat{X}' + \kappa \hat{X}^3
\end{pmatrix}.
\]
In the numerical simulations presented in this paper $\bar{\omega} = \pi/2$ and $\omega_x$ is chosen so that $\omega_x + \bar{\omega}$ has the correct value, i.e. near the half-integer resonance.

The other key ingredient for the novel extraction, in combination with the stable islands, is the tune variation. In the model used for the numerical simulations the horizontal tune is changed in the following way

$$
\omega_x(n) = \begin{cases} 
\omega_{x,a} + (\omega_{x,b} - \omega_{x,a}) \left( \frac{n - 1}{n_1 - 1} \right)^p & \text{if } n \leq n_1 \\
\omega_{x,b} & \text{if } n_1 < n \leq n_2 \\
\omega_{x,b} + (\omega_{x,c} - \omega_{x,b}) \left( \frac{n - n_2}{n_3 - n_2} \right) & \text{if } n_2 < n \leq n_3,
\end{cases}
$$

(5)

where $\omega_{x,a}, \omega_{x,b}, \omega_{x,c}$ are the initial, intermediate, and final tune values, respectively, $n_1, n_2, n_3$ represent the time of transition between the stage of resonance crossing and constant tune, constant tune and linear ramp to separate islands before extraction, and the time when extraction is ready to occur, respectively. Finally, $p$ is a parameter used to change the functional dependence of the tune variation on $n$ during the resonance crossing: it allows changing from a linear sweep to a power law, thus changing the speed of resonance crossing. All these parameters have not been fully optimised yet, and this point is the subject of further studies. The vertical tune is always kept constant in 4D simulations.

3 RESULTS OF NUMERICAL SIMULATIONS

3.1 Two-Turn Extraction

Starting from the lowest-order resonance, it is possible to use the half-integer resonance as the base for a two-turn extraction. In Fig. 1 the tune as a function of turn number is shown. The four points labelled with letters refer to the tune values at which the beam distribution is shown in Fig. 2. The computations are performed using the map (3).

![Hor. tune vs. Turn number](image)

Figure 1: Evolution of the tune used for the simulation of a two-turn extraction. The four points labelled with letters correspond to the tune values at which the beam distribution is shown in Fig. 2.

adiabatic capture inside the two stable islands is clearly visible. As the resonance is unstable, particles are repelled from the origin during the trapping stage. Therefore, only a small fraction of particles remains near the origin, while the majority of them migrates to the islands as the tune is swept through the half-integer resonance. Once the two beamlets are created, it is possible to move the islands towards higher-amplitudes, hence increasing the beamlets separation so to prepare for extraction.
Figure 2: Beam distribution during the trapping process with two islands ($8.1 \times 10^5$ initial conditions). The initial distribution is a Gaussian centred on zero, with a standard deviation $\sigma = 0.11$, $\kappa = -1$. Only a few particles are left near the origin of phase space.

3.2 Three-Turn Extraction

In this case the model (2) is used in the numerical simulations. The time-evolution of the linear tune is presented in Fig. 3, while the evolution of the beam distribution is shown in Fig. 4.

Figure 3: Evolution of the tune used for the simulation of a three-turn extraction. The four points labelled with letters correspond to the tune values at which the beam distribution is shown in Fig. 4.

Also in this case the resonance is intrinsically unstable, thus making it possible to deplete almost perfectly the region near the origin of phase space. Three beamlets represent the final result of the capture process.
Figure 4: Beam distribution during the trapping process with three islands ($8.1 \times 10^5$ initial conditions). The initial distribution is a Gaussian centred on zero, with standard deviation $\sigma = 0.04$, $\kappa = -5$. Even in this case very few particles are left in the central part of phase space.

3.3 Five-Turn Extraction

The fourth-order resonance is the one used in the original proposal [5] for a novel multi-turn extraction to replace the present CT extraction mode. As the fourth-order resonance is stable for the system (2), the beam will be split into five beamlets. The evolution of the tune is shown in Fig. 5. The evolution of the beam distribution is plotted in Fig. 6.

Figure 5: Evolution of the tune used for the simulation of a five-turn extraction. The four points labelled with letters correspond to the tune values at which the beam distribution is shown in Fig. 6.

The four outermost beamlets are created by adiabatic trapping inside the stable islands, while the fifth one is generated by those particles left unperturbed near the origin of

phase space. This fact has deep implications on the properties of the beamlets. In fact, for the previous multi-turn extraction processes (two- and three-turn) the various beamlets had exactly the same number of particles trapped inside as they represent a unique ribbon of length two or three times the machine circumference. On the other hand, whenever the central part of phase space remains filled at the end of the capture process, it is not necessarily equally populated as the other beamlets, unless a dedicated optimisation of the free parameters is performed. Such an optimisation concerns mainly the sigma of the initial beam distribution, the nonlinear elements strength, and the properties of the tune-variation. For this specific case, 4D simulations have been performed using the map (1). The results are shown in Fig. 7, where two projections of the 4D phase space, namely the physical phase space \((\hat{X}, \hat{Y})\) (left) and the vertical phase space \((\hat{Y}, \hat{Y}')\) (right) are shown. In the physical phase space three spots are clearly shown, as a result of projecting the two beamlets centred on \(\hat{X}' \neq 0\) onto the central one. The separation of the three spots can be adjusted by acting on the value of the final tune \(\omega_{x,c}\). In the vertical phase space almost no sign of coupling with the horizontal one, due to the nonlinear terms in the map (1), is visible. This confirms that the assumption of neglecting this degree of freedom is well justified.

Another test performed for this special case was the sensitivity of the capture process on the presence of tune modulation. This is an almost unavoidable effect in real machines. It is potentially harmful for the proposed multi-turn extraction because islands are shaken due to the periodic tune variation, thus inducing beam filamentation and emit-
Figure 7: Phase space projections: physical space ($\hat{X}, \hat{Y}$) (left) and vertical phase space ($\hat{Y}, \hat{Y}'$) (right) at the of the capture process with four islands as computed using the 4D map (1) with $\kappa = -1.5$ and $\chi = 0.5$. The vertical tune $\nu_y$ is 0.29.

tance growth. Numerical simulations have been carried out including a tune ripple of the form

$$\hat{\omega}_x(n) = \omega_x(n) [1 + a \cos (2 \pi f_{\text{ripple}} T_{\text{rev}} n)]$$

where $\omega_x(n)$ is the function (5). The parameters $a$, $f_{\text{ripple}}$, the ripple amplitude and frequency in Hertz, respectively, have realistic values for the CERN PS machine, i.e. $a$ about $10^{-3}$ and $f_{\text{ripple}}$ in the range $50 - 600$ Hz. $T_{\text{rev}}$ is the revolution time, which is about 2.2 $\mu$s for the PS machine at 14 GeV/c. The results are shown in Fig. 8. They confirm that

Figure 8: Dependence on the tune ripple of beam distribution at the end of the capture process, i.e. after $2 \times 10^4$ turns ($8.1 \times 10^5$ initial conditions) for different values of the ripple frequency. The initial distribution is a Gaussian centred on zero, with standard deviation $\sigma = 0.073$. The ripple parameters are $a = 10^{-3}$, and $b = 50$ Hz (left), 100 Hz (centre), 600 Hz (right).

the ripple is potentially harmful for the proposed extraction based on adiabatic capture. In fact, in all the cases shown in Fig. 8 the central beamlet is almost unaffected, while the four outermost beamlets show signs of degradation (emittance growth), visible in the form of an extended halo of particles surrounding the beamlets core. Of course, before
concluding on the quantitative effect of the tune ripple on the extracted beam parameters, a more realistic model of the accelerator for which the extraction is designed has to be used in the numerical simulations.

3.4 Six-Turn Extraction

It is possible to increase further the length of the extracted spill by using even higher-order resonances. Here, the case of a resonance of order five is shown in Figs. 9 and 10. However, it is clear that there are intrinsic limitations on the resonance order. In fact, the higher the order, the smaller will be the islands’ size, thus enhancing the difference between the first turns and the last one, represented by the particles left around the origin in phase space at the end of the capture process. Furthermore, it will be more and more difficult to create enough free space between the beamlets to accommodate the blade of an extraction septum.

Figure 9: Evolution of the tune used for the simulation of a six-turn extraction. The four points labelled with letters correspond to the tune values at which the beam distribution is shown in Fig. 10.

4 DIGRESSION: MULTIPLE MULTI-TURN EXTRACTION

From the results presented in the previous sections, it is clear that the number of extracted turns depends on the resonance order \( r \) and also on its stability. In fact, if the resonance is stable then the number of turns is equal to \( r + 1 \), otherwise it is simply \( r \). As far as the extraction is concerned, it would be somewhat more difficult for the case of stable resonances, as the amplitude of the orbit distortion needed to extract the various beamlets would be different, i.e. the same for the first \( r \) turns, but larger for the last turn. This point could be difficult to solve. Therefore, in this section alternative solutions are proposed, based on the idea that the adiabatic capture can be repeated by splitting the central beamlet remaining from the previous extraction.

As an example, a possible scenario is presented in Fig. 11. The key parameters, such as the number of particles, the value of the parameter \( \kappa \), and the horizontal tune, are plotted as a function of the turn number \( n \). The tune is periodically swept through the chosen resonance, in this case the fourth-order, so to capture periodically particles from the central beamlet. However, a problem appears, as the emittance of the beam core shrinks after each capture, due to the transfer and extraction of particles. To overcome this difficulty, two techniques can be used, namely i) change the parameter \( \kappa \), ii) increase artificially the beam emittance of the remaining beam core.

The first approach is shown in Fig. 11, where \( \kappa \) is increased. This is necessary as the islands’ size is proportional to \( \kappa \) and it increases with the value of the tune.
Just after crossing the resonant value, tiny islands are created near the origin: their size increases, as well as their separation, by moving the tune far apart from the resonance. As the central beamlet shrinks in size after successive multi-turn extractions, particles will experience the influence of smaller and smaller islands. Therefore, to capture enough beam it is necessary to increase the islands’ size by acting on the value of $\kappa$. The results of numerical simulations based on this principle are shown in Fig. 12. The letters refer to the corresponding tune value in Fig. 11. The different stages are clearly visible as well as the effect of size reduction of the central beamlet. The approach seems to work well, no particle is lost in the simulations, and the various beamlets are always well-separated without particles in between. Of course, a possible drawback could be the increasing strength of the sextupole and octupole, i.e. $\kappa$, required to capture beam in the successive multi-turn extractions.

The second approach, however, avoids increasing $\kappa$, as an appropriate emittance blow-up is applied to the central beamlet so to keep its size almost constant, even after successive multi-turn extractions. This is achieved by repeatedly kicking the beamlet when the tune is constant and back to its initial value, i.e. between stage (d) and (e) in Fig. 11. The results of numerical simulations are shown in Fig. 13. Even this approach seems to work well, without beam losses. The effect of the kicks used to blow-up the beam is clearly visible. The main advantage with respect to the previous solution is that in this case the nonlinear effects are not enhanced after each extraction.
Finally, we would like to add that other approaches could be applied to extract the central beamlet left as a result of an adiabatic capture performed with a stable resonance. Those previously described would allow a periodic sequence of multi-turn extractions. However, one could think of combining a particle trapping using a stable resonance, followed by an adiabatic capture performed using an unstable resonance. In this way, the whole beam would be extracted by means of only two steps.

5 CONCLUSIONS

In this paper various schemes for multi-turn extraction based on adiabatic capture of charged particles in stable islands of phase space were presented. By choosing the
Figure 12: Beam distribution during the multiple multi-turn extraction for the fourth-order resonance ($8.1 \times 10^5$ initial conditions). The initial distribution is a Gaussian centred on zero, with standard deviation $\sigma = 0.07$. The value of $\kappa$ is changed according to the curve shown in Fig. 11.
Figure 13: Beam distribution during the multiple multi-turn extraction for the fourth-order resonance ($8.1 \times 10^5$ initial conditions). The initial distribution is a Gaussian centred on zero, with standard deviation $\sigma = 0.07$, $\kappa = -1.5$, but the beam size is increased by repeated kicks after each extraction.
appropriate resonance, two-, three-, five-, and six-turn extractions have been computed. In all the cases shown here, particles can be trapped inside islands without any loss. Furthermore, it is possible to move the beamlets by acting on the tune so to increase their separation, which is the necessary condition to allow the actual beam extraction to take place. For the case of the five-turn extraction, detailed analysis including 4D simulations and study of influence of tune ripple on the beam parameters at the end of the capture process were performed. 4D simulations confirm that the neglected degree of freedom does not affect very much the final result, provided the vertical tune is chosen far away from low order resonances. Tune ripple is known to be potentially harmful as it tends to move islands and, during the capture process, this might lead to emittance growth of the beamlets. However, at least for the case of the ripple parameters used in this study, which represent reasonable values for the CERN PS machine, the net effect is acceptable. In case of stable resonances, multiple multi-turn extractions are possible, so to repeatedly split the beam core left over previous extractions. Two approaches have been presented, combining the necessary tune variation to sweep periodically through the chosen resonance, together with either an increase of $\kappa$ (to compensate for the shrinking of beam core) or repeated kicks used to blow-up the beam core. Both techniques seem to work well.

Last but not least, it is important to stress that the novel approach presented here, and applied to various type of multi-turn extractions, can be used also in the case of multi-turn injection by simply exploiting the symmetry under time-reversal of the models used in the numerical simulations presented in this paper.

Further studies are in progress to quantify a number of issues such as the condition for the capture process to be adiabatic, the optimisation of the tune variation, and the dependence of the extracted beam parameters on the strength of sextupole and octupole magnets\(^1\).

## A One-turn transfer maps

The 4D one-turn transfer map of a circular machine including localised sources of nonlinearities can be written as:

\[
\begin{pmatrix}
x \\
x' \\
y \\
y'
\end{pmatrix}_{n+1} = M \begin{pmatrix}
x \\
x' + f_x(x, y) \\
y \\
y' + f_y(x, y)
\end{pmatrix}_n,
\]

where \((x, x', y, y')\) is a vector in the 4D phase space representing the particle’s coordinates at the entrance of the magnetic elements generating nonlinear fields. \(M\) is a \(4 \times 4\) matrix in block diagonal form, namely

\[
M = \begin{pmatrix}
M_x & 0 \\
0 & M_y
\end{pmatrix}
\]

\(M_{x,y}\) being \(2 \times 2\) matrices. This form is certainly valid in case no sources of linear coupling, such as skew quadrupoles or solenoids, are present in the machine. Otherwise, it is always possible to decouple the linear matrix by using the formalism presented in Ref. [12].

\(^{1}\) In a completely different context, the analysis of particle trapping through nonlinear resonance was discussed in Ref. [16].
The functions \( f_x, f_y \) are related to the nonlinearities in the machine. By using the single-kick approximation, it is possible to show that \[9\]

\[
f_x(x, y) = \Re \sum_{n=2}^{m} \frac{K_n + iJ_n}{n!} (x + iy)^n,
\]

\[
f_y(x, y) = \Im \sum_{n=2}^{m} \frac{K_n + iJ_n}{n!} (x + iy)^n,
\]

where the coefficients \( K_n, J_n \), respectively the normal and skew normalised integrated multipole strengths, are defined by

\[
K_n = \frac{1}{B_0 \rho} \frac{\partial^n B_y}{\partial x^n} \ell, \quad J_n = \frac{1}{B_0 \rho} \frac{\partial^n B_x}{\partial x^n} \ell, \tag{10}
\]

with \( m \) the order of the highest multipole considered.

In Eq. (10), \( B_0 \rho \) stands for the magnetic rigidity of the reference particle, \( B_x, B_y \) are the transverse components of the magnetic field, and \( \ell \) is the physical length of the magnetic element. In the following it will be assumed that \( J_n = 0 \) for \( n \geq 2 \).

It is customary to change coordinates from physical to Courant-Snyder ones \[11\]. This is obtained by means of the linear, symplectic transformation:

\[
\begin{pmatrix}
\hat{z}' \\
\hat{z}
\end{pmatrix} = T_z^{-1} \begin{pmatrix}
z' \\
z
\end{pmatrix}, \quad T_z = \begin{pmatrix}
\sqrt{\beta_z} & 0 \\
-\frac{\alpha_z}{\sqrt{\beta_z}} & \frac{1}{\sqrt{\beta_z}}
\end{pmatrix}, \tag{11}
\]

where \( z \) stands for \( x \) or \( y \) and the quantities \( \alpha_z, \beta_z \) are the Twiss parameters \[11\] at the location of the nonlinear elements. The general 4D normalisation matrix \( T \) is in block diagonal form,

\[
T = \begin{pmatrix}
T_x & 0 \\
0 & T_y
\end{pmatrix}. \tag{12}
\]

By taking into account that

\[
R(\omega_x, \omega_y) = T^{-1} M T, \quad R(\omega_x, \omega_y) = \begin{pmatrix} R(\omega_x) & 0 \\ 0 & R(\omega_y) \end{pmatrix}, \tag{13}
\]

with \( R(\omega_z) \) a \( 2 \times 2 \) rotation matrix

\[
R(\omega_z) = \begin{pmatrix}
\cos \omega_z & \sin \omega_z \\
-\sin \omega_z & \cos \omega_z
\end{pmatrix}, \quad \omega_z = 2\pi \nu_z, \tag{14}
\]

the mapping (7) reads in the new coordinates:

\[
\begin{pmatrix}
\hat{x}' \\
\hat{x}
\end{pmatrix} = R(\omega_x, \omega_y) \begin{pmatrix}
\hat{x}' + \sqrt{\beta_x} f_x \left( \sqrt{\beta_x} \hat{x}, \sqrt{\beta_y} \hat{y} \right) \\
\hat{y}' + \sqrt{\beta_y} f_y \left( \sqrt{\beta_x} \hat{x}, \sqrt{\beta_y} \hat{y} \right)
\end{pmatrix} \tag{15}
\]

\[n+1\]
The general expression for the nonlinear kicks in the new coordinates can be obtained by using expression (9). In the computations presented in this paper only the first two terms, corresponding to the sextupolar and octupolar components, are taken into account:

\[ n = m = 2 \left\{ \begin{array}{l} \sqrt{\beta_x f_x} \left( \sqrt{\beta_x \hat{x}}, \sqrt{\beta_y \hat{y}} \right) = \frac{K_2}{2} \beta_x^{3/2} (\hat{x}^2 - \chi \hat{y}^2) \\ \sqrt{\beta_y f_y} \left( \sqrt{\beta_x \hat{x}}, \sqrt{\beta_y \hat{y}} \right) = -K_2 \beta_x^{3/2} \chi \hat{x} \hat{y}, \end{array} \right. \]  

\[ n = m = 3 \left\{ \begin{array}{l} f_x \left( \sqrt{\beta_x \hat{x}}, \sqrt{\beta_y \hat{y}} \right) = \frac{K_3}{6} \beta_x^2 (\hat{x}^3 - 3\chi \hat{x} \hat{y}^2) \\ f_y \left( \sqrt{\beta_x \hat{x}}, \sqrt{\beta_y \hat{y}} \right) = -\frac{K_3}{6} \beta_x^2 (\chi^2 \hat{y}^3 - 3\chi \hat{x}^2 \hat{y}), \end{array} \right. \]  

where \( \chi \) is a dimensionless parameter given by \( \chi = \beta_y / \beta_x \).

The next step consists in rescaling the Courant-Snyder coordinates so to set the coefficient of the quadratic term in (15) equal to one. By means of a non-symplectic transformation it is possible to define new dimensionless coordinates \((\tilde{X}, \tilde{X}', \tilde{Y}, \tilde{Y}') = \lambda(\hat{x}, \hat{x}', \hat{y}, \hat{y}')\) such that the one-turn map can be recast in the following form

\[
\begin{pmatrix}
\tilde{X} \\
\tilde{X}' \\
\tilde{Y} \\
\tilde{Y}'
\end{pmatrix}_{n+1} = R(\omega_x, \omega_y) \begin{pmatrix}
\tilde{X} \\
\tilde{X}' + \lambda \sqrt{\beta_x} f_x \left( \sqrt{\beta_x \tilde{X}}, \sqrt{\beta_y \tilde{Y}} \right) \\
\tilde{Y} \\
\tilde{Y}' + \lambda \sqrt{\beta_y} f_y \left( \sqrt{\beta_x \tilde{X}}, \sqrt{\beta_y \tilde{Y}} \right)
\end{pmatrix}_n
\]  

(18)

With the choice \( \lambda = 1/2K_2 \beta_x^{3/2} \) one obtains the following expression for the nonlinear kicks in Eq. (18)

\[ n = m = 2 \left\{ \begin{array}{l} \lambda \sqrt{\beta_x} f_x \left( \sqrt{\beta_x \tilde{X}}, \sqrt{\beta_y \tilde{Y}} \right) = \tilde{X}^2 - \chi \tilde{Y}^2 \\ \lambda \sqrt{\beta_y} f_y \left( \sqrt{\beta_x \tilde{X}}, \sqrt{\beta_y \tilde{Y}} \right) = -2\chi \tilde{X} \tilde{Y}, \end{array} \right. \]  

\[ n = m = 3 \left\{ \begin{array}{l} \lambda \sqrt{\beta_x} f_x \left( \sqrt{\beta_x \tilde{X}}, \sqrt{\beta_y \tilde{Y}} \right) = \kappa (\tilde{X}^3 - 3\chi \tilde{X} \tilde{Y}^2) \\ \lambda \sqrt{\beta_y} f_y \left( \sqrt{\beta_x \tilde{X}}, \sqrt{\beta_y \tilde{Y}} \right) = -\kappa (\chi^2 \tilde{Y}^3 - 3\chi \tilde{X}^2 \tilde{Y}), \end{array} \right. \]  

(20)

with

\[
\kappa = \frac{2}{3} \frac{K_3}{K_2^2} \frac{1}{\beta_x}.
\]  

(21)
The expression of higher-order multipoles in the final coordinates can be obtained easily by means of the following substitution

$$\frac{K_n + iJ_n}{n!} \rightarrow \frac{2^{n-1}}{K_2^{n-1} \beta_x^{\alpha_n-1}} \frac{K_n + iJ_n}{n!}.$$  \hspace{1cm} (22)

### B Fixed points

In this section some theorems concerning fixed points of a special class of 2D symplectic maps derived in Ref. [13] will be reported. They are based on results discussed in Refs. [14, 15].

A symplectic map \( F \) of \( \mathbb{R}^{2n} \) is called \textit{reversible} if it is the product of two \textit{involutions}, namely

$$F = I_1 \circ I_2 \quad \text{with} \quad I_1^2 = I_2^2 = I,$$  \hspace{1cm} (23)

where \( I \) is the identity matrix in \( \mathbb{R}^{2n} \). Such a factorisation imposes constraints on the existence and location of the fixed points and can be used to simplify the problem of their computation. A point \( x \) is called a \textit{fixed point} of \( F \) if it satisfies the equation

$$F(x) = x.$$  \hspace{1cm} (24)

Similarly, fixed points of order \( m \), or \( m \) cycles, can be defined as the fixed points of the \( m \)th iterate of the map

$$F^m(x) = x, \quad \text{where} \quad F^m(x) = F(F(F(\cdots F(x)\cdots))) \quad \text{\( m \) times}.$$  \hspace{1cm} (25)

One can prove that [13]

**Theorem 1.** Given a symplectic map \( F \) of \( \mathbb{R}^{2n} \) such that \( F = I_1 \circ I_2 \) with \( I_1, I_2 \) two involutions, if \( x \) is a point of \( \mathbb{R}^{2n} \) satisfying

$$\begin{align*}
I_1(x) & = x \\
I_2(F^m(x)) & = F^m(x)
\end{align*}$$  \hspace{1cm} (26)

then \( F^{2m+1}(x) = x \).

Similarly, if \( x \) is a solution of one of the two systems

$$\begin{align*}
I_1(x) & = x \\
I_1(F^m(x)) & = F^m(x)
\end{align*} \quad \begin{align*}
I_2(x) & = x \\
I_2(F^m(x)) & = F^m(x)
\end{align*}$$  \hspace{1cm} (27)

then \( F^{2m}(x) = x \).

In the case of 2D one-turn maps of the form described in Appendix A, it is easy to show that they can be decomposed into two involutions, with \( I_1 \) and \( I_2 \) being a linear and nonlinear transformation, respectively

$$I_1 = \begin{pmatrix}
\cos \omega_x & -\sin \omega_x \\
-\sin \omega_x & \cos \omega_x
\end{pmatrix}, \quad I_2(x, x') = \begin{pmatrix} x \\
-x' - P_r(x)
\end{pmatrix},$$  \hspace{1cm} (28)
where $P_r(x)$ is a polynomial of order $r$ representing the effect of the kicks due to the nonlinear elements. It is easily seen that $\mathcal{I}_1$ represents a reflection about the line $x' = -x \tan \omega x / 2$, the locus of fixed points of $\mathcal{I}_1$. Similarly, the locus of fixed points of $\mathcal{I}_2$ is given by curve $x' = -1/2P_r(x)$.

Under these hypothesis it is possible to prove that the following stronger results hold [13]

**Theorem 2.** Let $F$ be a planar symplectic map factorised into involutions $\mathcal{I}_1, \mathcal{I}_2$ of the form given in Eq. (28). Then $x$ is a fixed point of $F$ iff it satisfies

$$
\begin{cases}
\mathcal{I}_1(x) &= x \\
\mathcal{I}_2(x) &= x.
\end{cases}
$$

(29)

The geometrical interpretation of this Theorem is that the fixed points of period one are exactly the intersections of the loci of the fixed points of the two transformations $\mathcal{I}_1, \mathcal{I}_2$ into which the map $F$ is decomposed.

A similar result holds for the fixed points of $F^{o2}$

**Theorem 3.** Let $F$ be a planar symplectic map factorised into involutions $\mathcal{I}_1, \mathcal{I}_2$ of the form given in Eq. (28). Then $x$ is a fixed point of $F^{o2}$ iff it fulfils the following condition:

$$
\begin{cases}
\mathcal{I}_2(x) &= x \\
\mathcal{I}_2(F(x)) &= F(x).
\end{cases}
$$

(30)

Condition (30) means that if both the initial point $x$ and its image under $F$ belong to the locus of the fixed points of $\mathcal{I}_2$, then $x$ is a fixed point of $F^{o2}$. However, the action of $F$ on a fixed point of $\mathcal{I}_2$ is simply a reflection about the fixed line of $\mathcal{I}_1$. Therefore, provided trivial solutions, i.e. fixed points of $F$ are disregarded, for a fixed point of period two to exist the locus of fixed points of $\mathcal{I}_2$ must contain at least one point together with its reflection about the fixed line of $\mathcal{I}_1$. It is easily seen that this can never be the case for maps of the form (2).

To overcome this difficulty the initial map has to be modified so to break the symmetry and the factorisation into the two involutions $\mathcal{I}_1$ and $\mathcal{I}_2$. This can be obtained by separating the two sources of nonlinearities, i.e. sextupole and octupole magnets, hence inserting a linear matrix between the two nonlinear kicks, as it is the case with the new map (3).
